More recent views see emotions as intrinsically interwoven with moral thought in a complex web of interactions (see Figure 12.4). Emotions such as empathy, anger, shame, and fear may often provide our most rapid moral intuitions, with rational judgments coming into play only afterward (Haidt, 2003; Prinz, 2004, 2007; Singer, 2005). Historically, many philosophers, such as the British empiricist David Hume (1739/2007), have seen emotions as the basis for moral action. Of course, emotions themselves may have cognitive components (see Chapter 7), but the moral emotions view shifted the focus from complicated moral deliberations about harm and benefits to simpler and quicker emotion-driven intuitions. Variations of the view of emotions as the basis for moral actions are very much in evidence today (Eisenberg, 2000; Haidt, 2012; Hoffman, 2000; Kagan, 1994). Indeed, some argue that deliberate, well-thought-out consideration of moral situations is simply too slow and requires too much thought to govern the daily rush of situations that call for action; they believe that we need faster, noncognitive means to respond "on the fly" (Haidt, 2001, 2003; Haidt & Kesebir, 2010). We often act so quickly and impulsively that it is difficult to see the basis of such actions as lying in well-thought-out moral reasoning.

The claim that cognition about moral situations is slow, however, assumes that we do all our moral computations only after entering a situation and appraising it. Instead, we may consider various types of situations in advance, building up elaborate moral schemas ready to be enacted in an instant response that requires little real-time thought. All of us have entered situations to which we have given much thought in advance and to which we can respond very rapidly based on our prior cognition. For example, if your roommate repeatedly fails to take her turn doing the dishes, you may have a prepared, readily available response the next time she shirks the job. This view suggests that there is a constant dynamic interaction between emotional and cognitive factors in the determination of most actions. Emotions may make certain patterns of reasoning more salient or available, and patterns of reasoning may trigger certain emotions. Thus, one type of moral thought does not necessarily cause the other; rather, both types continuously elaborate and inform each other, especially in complex social situations (Dunn, 2006).

In addition, patterns of reasoning can help encode or frame an action as being part of the moral realm or belonging to a particular sphere of morality, such as a concern with purity (Cushman & Young, 2011). Some researchers talk about a process of "moralization," in which cultural beliefs and customs and certain networks of causal beliefs can cause a pattern of behaviors to enter the moral realm. The act of smoking may be one such example of an action initially seen as a custom that became moralized in many areas of North America (Rozin, 1999; see Figure 12.5). More broadly, cultures can expose children to certain schemas and causal interpretations that can powerfully shape whether actions even elicit moral emotions (Sachdeva et al., 2011).

FIGURE 12.4 Cognitions versus emotions as the basis for moral judgments. For centuries, scholars have disagreed as to whether moral judgments are grounded in rational thought about principles, as in **(A)** *Star Trek*'s fictional Spock, or in moral emotions, as in **(B)** the obvious empathy shown by St. Francis of Assisi. Related questions ask about the relative roles of emotions and cognition at various points in a child's development.

Most of the foundational work on children's moral development emphasizes the cognitive component of moral thought and the child's growing understanding of rules and principles for guiding moral reasoning. These views often carry the developmental implication that moral judgment is the highest form of morality and that the most virtuous people are those most able to rely on cognitive factors and not on other factors in making judgments (Kohlberg, 1984). In these early theories, moral development consists of increasingly being able to act on the basis of reasoned moral judgments, with the youngest children being most ruled by other factors, such as their emotions. These early views include stages of moral development in which children's thinking about rules and moral judgments changes with age; they were first proposed by Jean Piaget in his theory of moral development, followed by the stages proposed by Lawrence Kohlberg and Carol Gilligan. We will discuss each of these theories in turn and ask how they differ. Recent research has stressed a pluralistic approach in which an individual draws on different forms of moral thought in different contexts at all ages and may not pass through stages as such. Moreover, today scholars have shown that emotions continue to have a central role throughout development.

Q: What are three different views of the importance of emotions in moral thought?

Piaget's Theory of Moral Development

As in many other areas, we start by looking at Piaget's work on cognitive development. In considering the development of moral thought, we encounter many familiar issues. For example, we consider whether children progress through qualitatively distinct stages of moral reasoning, and if so, whether those stages resemble the developmental stages proposed in other domains. We also ask whether moral thought should be considered as a single, unified domain or as a collection of narrower domains with their own distinct properties and developmental patterns. Finally, we consider some of the ways that the development of moral thought varies across individuals and whether some core components of moral thought might be common to all cultures.

When Piaget devised his theory of moral development, he intended to incorporate it into his broad, comprehensive theory of the stages of cognitive development (Piaget, 1932/1965). He argued that moral thought is not a separate cognitive domain with its own patterns of reasoning and developmental course. Instead, he believed that moral development shares the same broad features that he attributed to other areas of cognitive development, including the notion of stages. Thus, according to Piaget, some patterns of moral reasoning are simply unavailable to children until they reach the relevant stage of moral development.

Piaget studied moral development from several perspectives. Most notably, he examined children's understanding and use of rules, their judgments of culpability and guilt, and their understanding of justice. Each of these lines of investigation has spurred extensive moral development research by others.

Q: How did Piaget's broad theory of cognitive development relate to his perspective on moral development?

Piaget's Stages of Moral Reasoning

Piaget began his study of young children's morality by observing how they play simple games. Specifically, he saw a close link between children's moral beliefs and the way they use a game's rules. Based on their behaviors at play, Piaget inferred links between children's use of rules and the stages of moral reasoning they had attained. Piaget proposed three stages of moral development, roughly corresponding to his stages of preoperational, concrete operational, and formal operational thought (see Table 12.1).

Stage 0: Premoral Development Until around 4 years of age, children's play seems to be simply for the fun of the activity, without any apparent use of rules. Piaget saw the child in this stage as unaware that rules exist and treating games like any other social activity. A child in the premoral stage might imitate older children playing the same game, but without understanding that set guidelines govern the way the game is played. Children at this age supposedly do not assess culpability or have intuitions about justice.

Stage 1: The Heteronomous Stage Piaget believed that children spend the years from about age 4 to 10, after toddlerhood and throughout the preoperational period and much of the concrete operational period, in the **heteronomous stage**. *Heteronomous* means governed by an external set of laws or control, and in Piaget's view, children in this stage see rules as inviolate and unalterable and having a kind of external reality like the laws of nature.

At the same time, Piaget observed that children in the heteronomous stage show evidence of egocentrism in their use of rules. They attempt to use standard rules and think that they are using them in consistent ways, but in fact, their use of rules is often highly idiosyncratic. They often modify or even make up rules, which they then assume are the general rules of the game. Anyone with a younger sibling can remember frustrating attempts to play a game with the younger brother or sister who adopted idiosyncratic rules, often to his or her own advantage, while seemingly remaining unaware that these rules differed

Stage	Name of Stage	Approximate Age	Reasoning about Rules
0	Premoral development	Up to 4 years	There is no explicit awareness of rules, no use of moral principles or notions of justice.
1	Heteronomous stage	4 to 10 years	Rules are seen as unchanging and external, like physical laws. Judgments of culpability are based on the act's consequences rather than the actor's intentions. There is little sense of what punishment is appropriate for what degree of transgression.
2	Autonomous stage	10 to 11 years and older	Rules are seen as human agreements that can be changed if all parties consent. Judgments of culpability are based in part on intentions, and punishment should be appropriate to the severity of the transgression.

TABLE 12.1 Piaget's stages of moral reasoning. In Piaget's theory of moral development, children progressed through three stages of moral reasoning, with the first stage supposedly devoid of any awareness of moral rules, principles, or ideas of justice.

from the standard ones. The heteronomous stage is particularly striking because the same 5-year-old child who frequently breaks the rules or makes them up also believes that the rules are immutable and fixed for all time. The combination of these features creates the central phenomena of Stage 1.

Piaget believed that the way children think about the rules of a game resembles their thinking about moral principles, which could be construed as rules for behavior. In some of his best-known studies of moral development, a researcher described a series of moral scenarios to a child and asked the child to judge the culpability of the child in the story and to decide whether the main character had acted badly. The most interesting manipulation involved scenarios in which the character's intentions did not match the magnitude of consequences resulting from his actions. Consider the following pair of stories that Piaget used in his studies (see Figure 12.6):

> *Neutral Intentions, Major Negative Consequences:* A little boy who is called John is in his room. He is called to dinner. He goes into the dining room. But behind the door there was a chair, and on the chair there was a tray with fifteen cups on it. John couldn't have known that there was all this behind the door. He goes in, the door knocks against the tray, bang go the fifteen cups and they all get broken! (Piaget, 1932/1965, p. 118)
>
> *Negative Intentions, Minor Negative Consequences:* Once there was a little boy whose name was Henry. One day when his mother was out he tried to get some jam out of the cupboard. He climbed up on to a chair and stretched out his arm. But the jam was too high up and he couldn't reach it and have any. But while he was trying to get it, he knocked over a cup. The cup fell down and broke. (Piaget, 1932/1965, p. 118)

Thus, in some stories a character's good or neutral intentions had quite bad consequences, while in others a character's bad intentions brought only slight negative consequences.

Most adults listening to Piaget's stories focused on the characters' intentions and decided that the child with the most negative intentions was guiltiest, even though the consequences of his behavior were much less severe. In contrast, children in the heteronomous stage seemed to ignore intentions and focus only on the consequences. They believed that the well-intentioned child who broke many cups was guiltier and more deserving of punishment than the ill-intentioned child who broke only one cup.

Here, for example, are responses by a 6-year-old named Geo to questions that were asked by an interviewer in that classic study:

Interviewer: What did the first boy do?
Geo: He broke eleven cups.
Interviewer: And the second one?
Geo: He broke a cup by moving roughly.
Interviewer: Why did the first one break the cups?
Geo: Because the door knocked them.

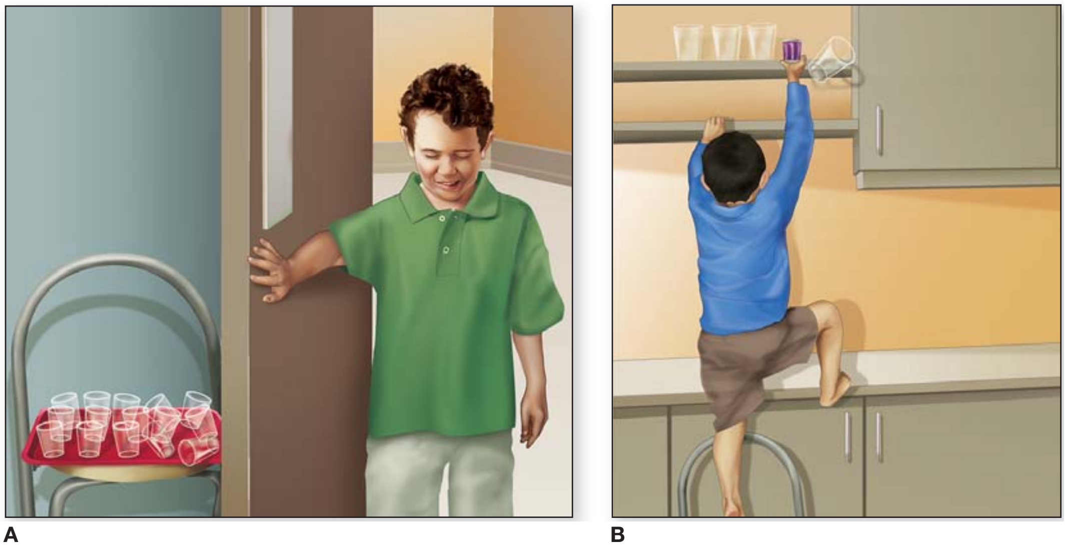

FIGURE 12.6 Scenarios used by Piaget to elicit children's moral reasoning. In the heteronomous stage, children tend to judge consequences as more important than intentions. Thus, they judge **(A)** a child who accidentally causes 15 glasses to break as more guilty than **(B)** a child who accidentally causes 1 glass to break, despite the fact that the first child did not intend to do anything wrong, but the second child did have a negative intention (reaching for jam that was deliberately placed out of his reach).

Interviewer: And the second?
Geo: He was clumsy. When he was getting the jam the cup fell down.
Interviewer: Is one of the boys naughtier than the other?
Geo: The first is because he knocked over twelve cups.
Interviewer: If you were the daddy, which one would you punish most?
Geo: The one who broke twelve cups.
Interviewer: Why did he break them?
Geo: The door shut too hard and knocked them. He didn't do it on purpose.
Interviewer: And why did the other boy break a cup?
Geo: He wanted to get the jam. He moved too far. The cup got broken.
Interviewer: Why did he want to get the jam?
Geo: Because he was all alone. Because his mother wasn't there.
Interviewer: Have you got a brother?
Geo: No, a little sister.
Interviewer: Well, if it was you who had broken the twelve cups when you went into the room and your little sister who had broken one cup while she was trying to get the jam, which of you would be punished most severely?
Geo: Me, because I broke more than one cup.
(Piaget, 1932/1965, pp. 120–121)

Piaget further argued that children in this stage reason the same way in making moral judgments about lies. Thus, after hearing similar stories, the children judged making a very false claim without intending to deceive (for example, being mistaken) as worse than purposely telling a small lie to deceive. To Piaget, these patterns suggested that younger children are unable to take into account intentions in evaluating the morality of actions, making them incapable of mature moral reasoning.

Piaget was also concerned with younger children's beliefs in **immanent justice**, a kind of magical thinking in the heteronomous stage in which accidents are seen as cases of divine retribution. For example, a person steals an apple, and then while he is walking home a bridge collapses beneath him. Piaget argued that younger children are much more likely to see the collapse of the bridge as a kind of justice caused by God or spirits, rather than as a mere accident.

The Transition between Stage 1 and Stage 2 Piaget described a transition in children's thinking about both game rules and morality that occurs between the ages of about 7 and 11. He saw children as becoming more concerned with winning games and realizing that maintaining uniform rules is central to that goal. Thus, they start to honor standard rules and feel that others should as well. In this transition period from Stage 1 to Stage 2, children also start to weigh intentions more in judging culpability, and they become more aware of what is fair and how the severity of a punishment should relate to the transgression. Even so, their behavior in this period remains somewhat inconsistent. Piaget observed that they do not follow the rules perfectly, and their thinking still shows elements of Stage 1 moral reasoning as well.

Stage 2: The Autonomous Stage Finally, when children reach the **autonomous stage** at around age 10 or 11, they see rules as human conventions. Thus, children come to understand that people create rules for the purpose of organizing an interaction and that people can change the rules as well. According to Piaget, when children reach this stage, they begin to realize that moral principles are not a set of external laws. They come to understand that morals arise from group norms and from convictions based on individuals' beliefs and that intentions are central to judgments of culpability and consequences are of less importance. Piaget believed that by this stage, children have well-developed notions of fairness and appropriate justice. They understand that a punishment should be appropriate to a transgression, not arbitrarily harsh. Children's belief in immanent justice also diminishes, as they realize that bad things happen to good people (and vice versa) and that accidents should not be interpreted as punishments or rewards from an external agent.

Evaluating Piaget's Account

Piaget launched an important and highly active area of research on moral reasoning. In the process, he invented the influential technique of presenting children with moral situations and asking them to evaluate guilt. His account of moral development captures some of the important patterns of change in children's use and understanding of rules. Research has shown that once children become aware of rules, they often become excessively rigid in how they apply them. In many studies, children at around 7 years of age latch on to rules as inviolate and unchangeable, only to later understand how and why they might be malleable. Some of Piaget's observations about children's moral judgments also pick up on real-world developmental phenomena. Younger children do sometimes fail to take intentions into account in their moral judgments, and they can have difficulty calibrating the appropriate level of punishment for an action, but neither of these abilities is as limited in young children as Piaget thought. More generally, Piaget pioneered a truly cognitive approach to the development of morality, and in doing so, he helped all later researchers explore the limits of a purely cognitive approach uninfluenced by emotions. At the same time, however, there are concerns about whether several of his studies were really focusing on the moral domain and its unique properties.

Distinguishing Morality from Conventions One possibility that corresponds to discussions in earlier chapters is that young children have more difficulty thinking about the kind of arbitrary patterns and rules typical of most games than they do about nonarbitrary functional patterns such as putting on their socks before their shoes. For example, whether card players deal from the deck clockwise or counterclockwise has no inherent meaning and little to do with which rules would be "most sensible"; both alternatives work equally well. Even so, the chosen rules must be honored to make the game work. Learning such arbitrary rules may be more difficult for young children, as the rules have little real-world significance to help explain them.

But Piaget's attempts to link children's understanding and use of game rules to morality also faces a deeper problem. Moral laws are very different from **social conventions**, which are arbitrary rules jointly agreed to by a group or a society to facilitate interaction and coordinate activity. The philosopher David Lewis has pointed out that social conventions have a different structure from moral laws, including the critical distinction that conventions are arbitrary and moral laws are not (Lewis, 1969). Take the convention of driving on the right side of the road in the United States, which is fully arbitrary; in other countries, such as Great Britain, drivers get along fine on the left side (see Figure 12.7). In contrast, the moral principle that people should be honest is not arbitrary, and it would be difficult to do business or even converse in a society where lies were the norm. Because game rules are largely arbitrary, they seem much closer to social conventions than to moral laws.

Interestingly, when researchers directly examined young children's ideas about social conventions, moral laws, and inviolable physical laws (like gravity), even preschoolers seemed to understand the essential differences (Lockhart et al., 1977). In one series of studies, preschoolers were told about situations in which a person violated either a social convention (drives on the wrong side of the road), a moral law (steals from others), or a physical law (floats in the air). Preschoolers tended to explain these transgressions in different ways, describing violators of social conventions as being "crazy," violators of moral laws as being "bad," and violators of physical laws as using "magic" (Lockhart, 1980). It therefore seems that Piaget overinterpreted younger children's difficulties with arbitrary game rules by assuming that they reflected broad problems using rules, including moral laws. In fact, children understand the differences between different kinds of rules at an early age, and they seem to have a sense of how moral laws differ from arbitrary rules (Turiel, 1983, 1998).

Q: In what ways does children's understanding of game rules differ from their understanding of social conventions?

Accounting for Intentions Piaget may have underestimated younger children's ability to account for people's intentions in evaluating actions. If, as Piaget claimed, children younger than about 10 could not take intentions into account in their moral judgments, they would be unable to see the difference between an accidental harm and a deliberate injury. We have seen, however, that even preverbal

FIGURE 12.7 **Social conventions versus moral laws.** Driving on a particular side of the road is an arbitrary social convention established by a society, as shown by **(A)** British drivers, who drive on the left side of the road, and **(B)** American drivers, who drive on the right side of the road. **(C)** Prohibitions against stealing would be considered moral laws in all societies.

infants seem acutely sensitive to others' intentions and goals (see Chapter 5). It would therefore be surprising if young children were so attentive to intentions early on, yet unable to use them to evaluate malice and culpability.

A closer look suggests that the differences in the ways that younger children and adults think about intentions may be more nuanced than Piaget believed. Researchers have thoroughly investigated the claim that younger children cannot take intentions into account, using a much wider range of stories and story formats than Piaget did. These studies have repeatedly uncovered cases where even preschoolers are fully capable of considering intentions, especially if intentions are described at the end of a story rather than at the beginning (Karniol, 1978; Keasey, 1978). If children are told to pay attention to intentions or if intentions are stressed in some way, young children often take them into account (Costanzo et al., 1973; Farnill, 1974; Keasey, 1978; Nelson, 1980). These findings suggest that varying the experiments might reveal circumstances in which young children would consider intentions. If there are no distracting differences in consequences, children might base their judgments on which intentions are better. Similarly, if positive consequences are pitted against neutral ones, the intentions might also become more salient. Finally, if researchers use videotapes or cartoons that make the differences in characters' intentions clearer, young children might be more likely to factor them into their moral judgments (Chandler et al., 1973). Thus, an extensive literature shows that in some situations, young children do have a clear awareness of intentions and their relation to morality (Baird & Astington, 2004).

Children may weigh consequences more than adults, but it may not be because of a marked developmental difference in moral understanding. Rather, younger children may be less skilled at discerning intentions or at keeping several aspects of a story in mind at once. Nonetheless, these differences do not mean that younger children reason about moral situations in fundamentally different ways than older children and adults. There are parallels here to Piaget's claims as to why young children fail at conservation tasks. As we saw in Chapter 9, rather than lacking certain logical reasoning skills that make conservation impossible, younger children simply may have more difficulty remembering the entire sequence of events and may focus too much on the final components of a chain of events.

Although preschool-age children are sometimes able to consider intentions, the question remains as to why, with increasing age, children can more easily take intentions into account. One possible explanation is based on **information integration theory**, which examines how children integrate different dimensions of a problem to gain understanding and make decisions. This theory argues that younger children often focus on one dimension of a problem (in the case of moral judgments, this could be either intentions or consequences), while older children are capable of integrating several dimensions at one time (both intentions and consequences in the case of moral judgments; Anderson, 1980; Anderson & Butzin, 1978).

Experimental tasks that involve manipulating several dimensions of moral judgment have supported this explanation of how children become increasingly able to take intentions into account (Baird & Astington, 2004; Zelazo et al., 1996). Nonetheless, these predictions cannot apply to all sorts of thinking and reasoning because, as we saw in Chapters 9 and 10, younger children sometimes have difficulty zeroing in on the critical dimension of a problem and instead will consider several at once. But at least in some cases, the developmental effects of information integration are evident, presumably in situations where the child has to weigh several dimensions against each other to reach an optimal decision.

Q: Why might young children have trouble taking intentions into account in judging the culpability of others?

Immanent Justice across Cultures Piaget's claim that younger children are more inclined toward magical thinking about rewards and punishments has also been challenged. Cross-cultural studies suggest that this may not be the best characterization of how moral thought develops. For example, more than 70 years ago, the renowned anthropologist Margaret Mead studied the development of magical thinking in traditional people in Papua New Guinea by asking them about the reasons for natural events (Mead, 1932). Contrary to some popular claims, younger children did not invoke more magical thinking than adults. Instead, they offered simple, concrete causal explanations, whereas adults tended to also invoke supernatural explanations involving spirits and gods. For example, if asked why a canoe floated away, a child might explain that it was not properly tied to a dock, while the elders might also say that certain spirits caused it to happen. In fact, when the younger children were offered metaphysical explanations instead of the more practical, mechanical ones, they rejected them. Sometimes it takes years of training in a culture's belief system before an individual will readily offer causal explanations that go beyond the physical, mechanical ones.

Q: What is Piaget's notion of immanent justice, and why has its developmental status been questioned?

Building on his research on children's use of rules, Piaget offered a general model of moral development that says that younger children do not take intentions into account in their moral judgments. Although his model no longer seems tenable, the idea of stages of moral reasoning remains influential, especially as it pertains to the work of Lawrence Kohlberg.

Kohlberg's Theory of Moral Reasoning

Lawrence Kohlberg approached the study of moral development with close attention to Piaget's work. Kohlberg believed that one mistake that trapped both Freudians and behaviorists was to not think seriously about what morality itself is. There was, for example, almost no attention from either of those camps to thousands of years of philosophical discourse as to what constitutes true virtue. For Kohlberg, beliefs about what is moral are not incidental, but rather central to the proper study of moral development and how children become moral thinkers—or what he called "moral philosophers."

Kohlberg believed that children construct morality by developing a system of beliefs about concepts like justice and individual rights. He thought that it takes a long time for children to develop accurate beliefs and reasoning patterns about morality and that early on, they confuse moral issues with other issues, such as power, coercion, and authority. This process of discovering which issues are truly moral formed the basis for Kohlberg's model.

Kohlberg's Stages of Moral Reasoning

Kohlberg initially proposed six stages of moral development to describe how children's basic concept of virtue changes. He then clustered these six stages into three larger levels of moral reasoning—preconventional, conventional, and postconventional reasoning—which loosely resonate with the stages of moral development that Piaget proposed. Both of their theories capture the idea of the child moving through stages of being unaware of rules, of using rules too literally, and of engaging in more abstract thought.

Kohlberg assessed children's level of moral development by using a method that he devised known as the **moral dilemma**. Kohlberg's moral dilemmas were short descriptions of morally ambiguous situations in which a character must make a difficult moral choice. After hearing the dilemma, the study participant is asked which course of action is morally superior and why. Piaget and earlier researchers had also used stories to pose moral questions and elicit children's judgments, but Kohlberg's key innovation was to focus on the child's pattern of reasoning about the situation rather than on the judgment itself. Kohlberg's dilemmas also featured difficult situations about which morally sophisticated people could honestly disagree.

The most famous dilemma concerns a sad figure named Heinz, who had to decide whether to steal a drug to save his wife's life:

> In Europe, a woman was near death from a special kind of cancer. There was one drug that the doctors thought might save her. It was a form of radium that a druggist in the same town had recently discovered. The drug was expensive to make, but the druggist was charging ten times what the drug cost him to make. He paid $200 for the radium and charged $2,000 for a small dose of the drug. The sick woman's husband, Heinz, went to everyone he knew to borrow the money, but he could only get together about $1,000 which is half of what it cost. He told the druggist that his wife was dying and asked him to sell it cheaper or let him pay later. But the druggist said: "No, I discovered the drug and I'm going to make money from it." So Heinz got desperate and broke into the man's store to steal the drug for his wife. Should the husband have done that? (Kohlberg, 1963, p. 19)

For this dilemma, many arguments could support moral approval or disapproval of Heinz's action. According to Kohlberg, certain kinds of arguments, both for and against his choice, typify each stage of moral development.

In Kohlberg's first level of moral reasoning, the *preconventional level* (Stages 1 and 2), a child believes that someone is virtuous if she is not punished much for her actions or does not suffer much compared with her gains. Thus, a child in Stage 1 might say that it is not appropriate to steal the drug because Heinz will be punished harshly for theft. Another child in Stage 1 might say that it is appropriate to steal the drug because Heinz will get a much worse punishment if he lets his wife die. Both responses are considered typical of Stage 1, regardless of the particular moral choice, because in both cases avoiding punishment is the key concern. Children in Stage 2 might say that it is acceptable to steal the drug because it is worth spending some time in jail to keep your wife alive. Or they might say that it is not acceptable to steal the drug because the jail time would not be worth it given that his wife is so sick that she might die anyway.

To a child in the *conventional level* of moral reasoning (Stages 3 and 4), being virtuous means doing what we are told or conforming to group norms. Children in Stage 3 might say that it is acceptable to steal the drug because a nice person does not let his wife die, or they might say that it is not acceptable because only bad people steal things.

Stage 4 involves reference to law and order. The Stage 4 argument against stealing the drug is simply that Heinz is wrong to break the law, whereas arguments in favor would allude to following implicit, natural laws about not letting others die.

People who reach the final, *postconventional level* (Stages 5 and 6) believe that being virtuous means adhering to a "higher" principle of justice or fairness than either society or the individual's own interests dictate. Stage 5 arguments appeal to group norms, such as a group belief that it is acceptable to steal to save a life—or a society's belief that theft cannot be tolerated, no matter the cost. Finally, Stage 6 reasoning refers to the individual's own internal moral standards. Thus, a Stage 6 reason for stealing the drug is that the individual will not be able to live with himself if he lets his wife die. And a Stage 6 argument against stealing the drug is that stealing violates the individual's own beliefs about never stealing. Table 12.2 shows Kohlberg's three levels of moral reasoning divided into six stages.

Evaluating Kohlberg's Theory

Kohlberg's theory has been extremely influential in the field of moral development. His ideas served as the basis for hundreds of studies exploring how children and adults reason about complex moral problems. By considering people to be "moral philosophers," Kohlberg helped researchers focus on the reasoning processes related to moral thought rather than the specific moral choices. In addition, as researchers examined moral development across cultures, they often found support for the developmental patterns Kohlberg proposed. Younger children do tend to focus on immediate consequences, such as punishment, while older children and adults tend to focus more on principles governing the social interactions in a community, such as the Golden Rule (Gibbs et al., 2007).

As in Piaget's theory, Kohlberg's stages of moral development were supposed to be an invariant sequence in which each stage necessarily built on the one before. He contended

Level	Stage	Approximate Ages	Moral Principle	Kinds of Reasoning
I. **Preconventional morality:** Arises from basic needs and drives.	1	2 to10 years	Obedience and punishment orientation	Moral judgments are driven by a need to avoid punishment.
	2	2 to10 years	Instrumental-relativist orientation	Moral judgments are driven by the desire to meet personal needs.
II. **Conventional morality:** Arises from conforming to expected roles and pleasing others.	3	9 years and older	"Good boy/good girl" orientation	Moral judgments are driven by a need to be accepted by others as a good person.
	4	9 years and older	Law and order orientation	Moral judgments are driven by a desire to adhere to the letter of the law or to authorities.
III. **Postconventional morality:** Arises from abstract principles that transcend individual circumstances and local cultural contexts.	5	12 years and older	Social contract orientation	Moral judgments arise from adherence to laws that are set up as social contracts for the common good.
	6	12 years and older	Principled conscience-driven orientation	Moral judgments arise from adherence to personal principles, such as the Golden Rule.

TABLE 12.2 Kohlberg's stages of moral development. Each of Kohlberg's three levels of moral reasoning is divided into two stages. Kohlberg argued that each of these six stages shows distinctive patterns of moral reasoning. Although Kohlberg later revised his theory to add and later eliminate a stage, we present here his original six stages, which are the most widely known version of his theory. Adapted from Kohlberg (1976).

that a child has to progress through each stage to reach the next one. Yet, if you look closely at the reasoning at each stage, it is not clear how each stage logically forms the basis for the next one. Why, for example, should a concern with avoiding punishment (Stage 1) lead to a concern with how to meet personal needs (Stage 2)? These issues and several others have led to three types of criticisms of Kohlberg's theory: unclear stages, cross-cultural variations, and possible gender biases.

Unclear Stages The stages in Kohlberg's model are less clear-cut than they might initially seem. Kohlberg and his associates developed a long, complex test manual and set up training sessions to teach other psychologists the nuances of the scoring procedure. The indeterminacies in their scoring system led to many controversies and even to some revisions to the theory. Kohlberg later added a new Stage 7 and a partial Stage 4.5, then still later combined Stages 5 and 6, reducing the total number of stages to five (Colby & Kohlberg, 1987). The elaborate scoring system raised concerns about the extent to which most researchers could reliably agree on assigning judgments to specific stages (Krebs & Denton, 2005; Kurtines & Greif, 1974).

Researchers have also found that responses to moral dilemmas vary more than Kohlberg's model suggests. According to his theory, a typical kindergartner can evaluate a moral choice only in terms of how much he might suffer for his actions. In fact, even the youngest children do not show these strict limitations and sometimes reason at the highest levels. In addition, it is not uncommon for a child to respond to Kohlberg's moral dilemmas with judgments that span several stages. Because children's answers do not consistently fall into one or two of Kohlberg's stages (Krebs & Denton, 2005), it is difficult to use his model to classify or compare people's levels of moral development. This problem would be easier to handle if most children's responses clustered in one stage despite a few responses from other stages, but in many cases a child's responses span four stages or more.

Kohlberg made an important advance by raising the possibility of several different modes of moral reasoning and by asking how those modes might vary with development. Subsequent studies suggest, however, that instead of a strict progression of stages, there may be a more diverse set of moral reasoning styles even in quite young children that vary as a function of context and culture. There may still be developmental changes in terms of which forms of reasoning are most salient or cognitively accessible, but children do not seem to be trapped exclusively in one stage at a time.

Cross-Cultural Variations Kohlberg claimed that his stages of moral development are universal across cultures throughout the world. Yet, researchers who evaluated Kohlberg's system were surprised to find that different cultures show quite different proportions of the population having reached the higher moral levels. For example, when researchers used Kohlberg's model to evaluate moral development in Turkey in the 1970s, the results seemed to suggest that most of the Turkish adult population never moved beyond Stages 1 and 2. According to the findings, only a tiny percentage reached Stage 6 (Kurtines & Greif, 1974). Kohlberg never showed evidence of having a political agenda or other ulterior motives for raising some cultures morally above others. Unfortunately, his scales seemed to do this anyway in that people in Western developed cultures tended to show higher average scores than did people in non-Western cultures.

There may also be a relationship between modes of moral reasoning and the different roles that people occupy in a culture. For example, in one classic study in a rural African community in western Kenya, two groups of men were studied who were similar in age, religion, education, and income but who differed in the extent to which they were called upon by their neighbors to settle disputes (Harkness et al., 1981). Those who were often chosen to settle disputes made more moral judgments at conventional levels, such as the law and order level, whereas those who were not called upon to settle disputes tended to give more judgments at the instrumental-relativist level. Thus, even when people are matched in age and a wide range of socioeconomic indicators, they may give different moral judgments as a function of the social roles that they typically occupy. When cultures are more heterogeneous in terms of such roles, there is a greater possibility of variation in kinds of moral judgments (Edwards, 1987).

Q: To what extent are the developmental patterns uncovered by Kohlberg found in other groups and cultures?

Possible Gender Biases When Kohlberg developed his moral reasoning scales in the 1950s, he based the stages on data he collected from middle-class boys. At first no one considered the consequences of not including data from girls. Matters changed dramatically in 1977, however, when Carol Gilligan argued that different kinds of moral reasoning might be more dominant in girls and women than in boys and men (Gilligan, 1977). In contrast to Kohlberg's stages, which emphasize justice, Gilligan believed that girls and women more commonly stress empathy and caring in their moral judgments. By failing to consider this gender difference, she argued, Kohlberg's scales make females look less morally developed than males. Gilligan contended that when this care-oriented dimension of morality is taken into account, girls and women show much more sophistication in their moral reasoning and males show less developed moral thought (Gilligan, 1979, 1982). We now turn to a discussion of Gilligan's theory of moral development to get a better sense of her views.

Alternative Theories of Moral Development

Concerns about Kohlberg's theories led to two other approaches. One, based on Gilligan's theory, preserved the idea of stages but shifted the focus away from justice and rights to care. Another, arising from several researchers, started to question the strength of stage effects and proposed that children of all ages might have multiple ways of construing moral situations; we will call this the pluralistic approach.

Gilligan's Theory of Moral Development

Gilligan proposed her own three-stage sequence of moral development in which females tend to progress more rapidly than males. Children start in a preconventional stage in which their own personal welfare is all that matters. They then move into a conventional stage in which empathy and care for others motivates a belief that self-sacrifice is an intrinsic good. Finally, in a postconventional stage, children combine care about themselves and care for others into an integrated moral reasoning system that takes into account both factors (see Table 12.3).

Here is how Gilligan described one of the main gender differences underlying her model:

> The moral imperative that emerges repeatedly in interviews with women is an injunction to care, a responsibility to discern and alleviate the "real and recognizable trouble" of this world. For men, the moral imperative appears rather as an injunction to respect the rights of others and thus to protect from interference the rights to life and self-fulfillment. (Gilligan, 1982, p. 100)

Gilligan believed that for women, moral rights and responsibilities occur in terms of relationships. Yet, despite her emphasis on care, concern, and empathy in women's moral thought, Gilligan did not put emotions at the center of her theory. Rather, like Kohlberg, she believed that there is a critical cognitive component to morality that is related to thinking about moral principles. For Gilligan, the fundamental organizing principle is that people should help others who are in need or distress, whereas for Kohlberg, the central principle is that people should treat each other fairly. Thus, both theories emphasize moral rules or laws that elicit a particular form of reasoning about many interconnected principles.

Like Kolhlberg's system, Gilligan's system has been scrutinized for evidence of consistent gender differences in moral development and for indications as to whether empathy or caring might be a more dominant mode of moral thinking in some non-Western cultures. Despite Gilligan's suggestion of a major gender bias in Kohlberg's work, in almost 90 percent of roughly 100 studies of Kohlberg's stages of moral reasoning, no gender differences were found. In the remaining studies, sometimes males scored higher on moral reasoning, and sometimes females did (Walker, 1991, 2006).

The data on possible gender differences in the morality of caring is less clear, because few major studies of large samples have been conducted (Turiel, 1998). Over several studies, it appears that the vast majority of people use both care-oriented and justice-oriented forms of moral reasoning, relying on them for different questions and in different contexts. The evidence suggests that on average, females tend to use care-oriented reasoning more often, and males tend to use justice reasoning more often, and there are some indications that females can switch between the two forms of reasoning more easily (Haste & Baddeley, 1991; Jaffee & Hyde, 2000). But such differences in the frequency of use are quite modest and do not seem to represent a fundamental difference in males' and females' moral reasoning styles (Hyde, 2007).

If most people show both kinds of reasoning, further questions arise about how patterns of reasoning vary as a function of context. Perhaps males and females differ because they tend to be exposed to somewhat different types of situ-

TABLE 12.3 Gilligan's stages of moral reasoning. Gilligan's theory of moral development endorsed the idea of stages but shifted the focus to care.

Stage	Form of Reasoning
Preconventional	Individual survival is all that matters.
Conventional	Self-sacrifice is good in its own right and is driven by care for others.
Postconventional	Care about others and care about the self are integrated.

ations. Almost all moral judgments require an appraisal of the situation. If someone commits a questionable action, it may matter greatly to know more about whether he was compelled to do it, what others who were involved did, and so on. Even the same action, when interpreted by different people, can lead to contrasting judgments.

Finally, just as Kohlberg has been criticized for collecting data primarily from middle-class boys, Gilligan has been criticized for basing her theory on data collected from women attending elite colleges such as Harvard University. Studies that included women from a broader spectrum of socioeconomic groups, including women from various disadvantaged minorities, found much smaller differences between men and women in care-based and justice-oriented moral reasoning than Gilligan did. In these studies, justice-oriented reasoning often dominated among both sexes (Stack, 1986, 1990). In addition, in some cultures, care-based reasoning seems to take on a quite different way of thinking from that proposed by Gilligan. For example, in both Japan and India, when children talk about care, they talk less about interpersonal feelings and more about duties arising from various societal roles (Miller, 2006; Shimizu, 2001). Moreover, the care focuses more on communities and groups than on individuals (Jensen, 2008).

A Pluralistic Approach to the Development of Moral Thought

One consistent theme has emerged from recent research on moral development: the same person comes to rely on different patterns of moral thought, depending on the context. We will call this theme the "pluralistic approach," meaning that each individual is not bound to one or two forms of moral thought but instead may switch between several different forms as a function of the situation in which that person is embedded and how the situation is viewed. In this pluralistic view, moral development is not a simple linear progression through stages but rather an elaboration of several different modes of moral thought that are available at a given age as well as shifts in which ones are dominant in certain situations. Thus, some possible modes of moral thought might be reasoning about sharing, helping others, modesty, defeat, or privacy (Smetana, 1997). This theme draws heavily on ideas in two subfields of psychology: personality psychology, which emphasizes how situations influence behavior, and cultural psychology, which emphasizes the social construction of belief systems.

Contributions from Personality Psychology One major focus in modern-day personality psychology is the study of person-situation interactions (Bem & Allen, 1974; Bem & Funder, 1978; Mischel, 1968), which also affect moral thinking. In personality psychology, person-situation interactions reveal that personality traits such as shyness can vary dramatically as a function of the situation in which a person is embedded. Various studies have shown that, like adults, children switch between different styles of reasoning, depending on the context. In one study, for example, stressing interpersonal relationships caused more care-based reasoning as opposed to justice-based reasoning (Smetana et al., 1991). Thus, if children heard stories in which a moral transgression was described as occurring between siblings, care-based reasoning was more prominent than when the same transgression was described as occurring between more casual acquaintances. The notion of group and individual differences in moral reasoning must therefore take into account theories of how moral reasoning interacts with social contexts. Just as it has become common to talk about how personality traits vary across situations and contexts, styles of moral reasoning may be similarly linked to situations and contexts.

Contributions from Cultural Psychology The modest differences in moral reasoning across sexes and the more notable variations across cultures have led some researchers to suggest that, contrary to Piaget's and Kohlberg's theories, moral universals may be exaggerated if they are understood to be the same stepwise progression of moral reasoning in all cultures. In some cases, moral systems may be culturally specific in ways that outsiders find difficult to understand. Thus, those who view moral development as more culturally relative consider the highest levels of Kohlberg's stages as too culture specific and simply irrelevant to many non-Western cultures (Shweder, 1982).

One major cultural difference that can affect moral reasoning involves the way that cultures prioritize the rights and well-being of individuals versus the rights and well-being of groups. In **individualist cultures**, the rights of the individual are supreme and favored over group rights, whereas in **collectivist cultures**, the rights of the group are central and the individual's rights are subordinate to those of the group. In general, Western societies are considered more individualist, and American culture is often seen as the most extreme example. In contrast, non-Western societies (and some Western societies with socialist political systems) are considered more collectivist (Bronfenbrenner, 1970; Shweder & Bourne, 1982). These differences in emphasis between, say, the United States and Japan or between Australia and China are not disputed, but their implications for patterns of moral reasoning are less clear. Shweder and his colleagues argue that the contrast can lead to cultural differences in morality: in individualist cultures, morality is based on notions of individual rights; in collectivist cultures, morality is based on duties to the larger group (Shweder et al., 1987).

One systematic analysis of the development of moral reasoning in four countries, including two individualist cultures (the United States and Canada) and two collectivist cultures (China and India) suggests that the broad individualist versus collectivist contrast may not fully capture the cross-cultural variations in children's and adolescents' moral reasoning (Neff & Helwig, 2002). When they were asked to judge moral situations, the children and adolescents in these four cultures did show cultural differences in their moral judgments. But they also took situational features into account, which affected the patterns of cultural variation. For example, Indian boys were more likely to judge a husband's actions in individualist terms and a wife's actions in collectivist terms, while boys in other cultures showed less of a gender bias. Yet, the Indian boys still made individualist interpretations for wives in some situations. In a different context—moral decisions about the rights of children to have a say in their own course of academic instruction—the cultural differences went against the broad predictions of a collectivist versus individualist account, with Chinese adolescents putting more weight on the individualist rights of students and Canadian adolescents putting more emphasis on the larger system of education and the importance of deferring to authority. Rather than an individualist/collectivist contrast, the cultural differences in children's patterns of moral judgment supported a **constructivist approach** to moral reasoning, in which the child evaluates the situation and the actors and takes into account culturally specific meanings in order to construct an interpretation specific to that context (Turiel, 2002).

This evidence suggests that, just as sex differences in moral reasoning seem better understood in terms of the influences of social context, some cultural differences can also be better understood in terms of situational influences. Unfamiliar cultures may rely on similar underlying patterns of moral reasoning but express them in different ways, depending on the culture's particular distribution of social contexts.

Rather than there being no moral universals, it may be that we all share a universal set of moral reasoning patterns that manifest in different ways, depending on cultural and social contexts. Indeed, in a revision of his theory, Shweder suggested that all cultures may share three fundamental moral values—autonomy, community, and divinity—with each culture placing a different emphasis on each. Autonomy refers to notions of harm, rights, and justice as they bear on an individual's ability to meet his or her own needs. Community refers to notions of duty, social hierarchy, and mutual dependency as they bear on an individual's role and standing in a community. Finally, divinity refers to notions of natural and sacred orders, sanctity, sin and purity, and how they bear on the ability of a person to maintain spiritual integrity.

This view suggests that people in all cultures are capable of the same general moral reasoning patterns, but each person expresses them according to his or her own culture-bound contexts and ways of interpreting situations. For example, Americans are thought to emphasize autonomy most heavily and to de-emphasize community and divinity, whereas many groups in India seem to emphasize community and divinity most heavily and de-emphasize autonomy. Nonetheless, each of these three aspects of morality can be manifested in any culture, given the appropriate context (Shweder et al., 1998). More generally, it is difficult to support the claim that any particular culture completely lacks a certain form of moral reasoning, as opposed to just using it in fewer types of situations (Turiel, 1998).

The influence of social context on morality also bears on moral development. As Kohlberg's early work showed, a specific child's patterns of moral reasoning can span as many as five distinct stages (Kurtines & Greif, 1974). It has since become clear that children, like adults, take situational factors into account as they choose from a wide range of reasoning patterns. But this is not to say that moral reasoning does not change with development. Reasoning undoubtedly becomes more complex with age, and the higher stages typical of adolescents and adults often involve more complex reasoning than the early stages. Nonetheless, simple versions of fairness and the "Golden Rule," normally considered fairly sophisticated moral reasoning (corresponding to Kohlberg's Stage 6), seem to be within the grasp of young children.

Q: Describe how patterns of moral reasoning might vary across different social contexts.

Domain-Specific Moral Reasoning Piaget, Kohlberg, and Gilligan devised theories of moral development that generated enormous amounts of research. Still, their approaches have not exhausted the range of developmental paths to mature moral reasoning. Each of their approaches describes a progression of stages intended to apply to moral thought in all kinds of situations. More recently, some theorists have suggested models of domain-specific moral reasoning, in which moral reasoning is thought to occur in quite distinct modes that may be related to evolved systems governing self-protection and interpersonal interactions. The domain-specific approach is also quite compatible with the pluralistic perspective, in which different situations invoke different moral domains.

For example, William Damon believes that there may be a specific moral domain for reasoning about sharing and the justice of distributing resources to others and that it includes several stages that follow a developmental progression (Damon, 1980, 1990). Whether this progression really reflects a complete incompetence of younger children to think about sharing in certain ways or whether some kinds of reasoning tend to be more complicated and, when simplified, might still have cores that are accessible to much younger children remains to be studied. But Damon suggests that young children often neglect the extent to which one person might be more deserving in judgments about sharing. Above and beyond the details of the particular developmental progression, Damon's central idea is that development in the realm of sharing and resource distribution takes its own trajectory that is markedly different from the developmental path in other domains, such as those involving harm or lying.

Another domain-specific theory of moral reasoning focuses on prosocial reasoning—that is, how children think about cases of **altruism**, where an individual acts for the benefit of another at her own personal expense. Nancy Eisenberg has proposed that children's reasoning about altruistic actions includes a set of developmental stages that are roughly analogous to Kohlberg's (Eisenberg, 1986, Eisenberg et al., 2005). Eisenberg's stages of reasoning about altruism consist of a concern with immediate self-interest, seeking approval of others, and appealing to internalized principles. Yet, the stages are not presented as a rigid developmental sequence, but rather as a collection of forms of reasoning, most of which are available to an individual. In this view, the form of reasoning an individual uses to decide whether to act altruistically depends more on situational factors than on the person's age. In addition, prosocial reasoning seems to develop quite independently from reasoning about what is wrong (Eisenberg, 2000; Robinson et al., 1994). We will revisit prosocial morality later in this chapter when we consider how emotions such as empathy can guide behaviors differently than moral reasoning alone.

There may not be any particular type or stage of moral reasoning that is inherently so complex that it is fully unavailable to preschoolers. In fact, even very young children are able to access and appropriately use advanced forms of moral reasoning when the scenario is sufficiently simple and heavily linked to familiar contexts. This ability suggests that children may not actually undergo the kind of developmental progression through a series of moral stages that many theorists of moral development have described. Instead, children may show early difficulties with some kinds of moral reasoning because young children generally have more trouble reasoning about complex ideas—not because they are unable to understand the concepts at stake in these "higher" levels of moral reasoning (Gibbs et al., 2007).

In addition to being influenced by social contexts, moral thoughts of various forms are also linked to moral emotions, to automatic nonconscious thought, to neuroscience, and to primatology (Haidt, 2008). In many cases, moral intuitions seem to bypass slow deliberative thought (see box on moral dumbfounding). One version of these non-deliberative processes is shown in Table 12.4 (Haidt & Joseph, 2004). In this

Moral Modules	Harm/Care	Fairness/ Reciprocity	Ingroup/Loyalty	Authority/ Respect	Purity/Sanctity
Adaptive challenge	Protecting and caring for young, vulnerable, or injured kin	Reaping benefits of mutual cooperation with nonkin	Reaping benefits of group cooperation	Negotiating hierarchy, deferring to authority	Avoiding microbes and parasites
Proper domain (adaptive triggers)	Suffering, distress, or threat to kin	Cheating, cooperation, deception	Threat or challenge to group	Signs of dominance and submission	Waste products, diseased people
Actual domain (commonly encountered triggers)	Baby animals, cartoon characters	Marital fidelity, broken vending machines	Home sports teams	Bosses, respected professionals	Taboo ideas (communism, racism)
Characteristic emotions	Compassion	Anger, gratitude, guilt	Group pride, belongingness, rage at traitors	Respect, fear	Disgust
Relevant virtues [and vices]	Caring, kindness [cruelty]	Fairness, justice, honesty, trustworthiness [dishonesty]	Loyalty, patriotism, self-sacrifice [treason, cowardice]	Obedience, deference [disobedience, uppitiness]	Temperance, chastity, piety, cleanliness [lust, intemperance]

TABLE 12.4 Moral modules. One way of presenting the pluralistic view of morality argues that humans have five distinct moral modules that are shared with evolutionary ancestors. Human cultural and cognitive processes have elaborated on these basic modules, giving rise to moral emotions and to our notions of virtues and vices. Adapted from Haidt & Joseph (2007).

model, moral intuitions arise from **moral modules**, which are forms of moral reasoning that have evolved to deal with specific kinds of moral problems encountered by individuals and groups. Separate modules give rise to harm/care concerns, fairness/reciprocity issues, in-group/loyalty tensions, authority/respect perceptions, and purity/sanctity problems. Several kinds of primates show behavior consistent with these moral modules because of the ways they meet adaptive challenges. Likewise, humans have applied these same modules to modern-day contexts and have elaborated on them as the bases for moral virtues. This account of moral thought and behavior blends together evolutionary psychology, cultural influences, cognitive factors, and a clear sense of domain specificity. Domain specificity is indicated by the idea that different forms of moral thought are elicited by specific kinds of situations or domains. Haidt's approach also suggests a model of development in which the domains for which the module was initially evolved become extended into more culturally modern domains and become culturally interpreted in terms of virtues. In Table 12.4, these are shown as a shift from "proper domains" that are triggered because of evolutionary adaptations to "actual domains" that are triggered by more recent cultural factors as well.

The Development of Moral Behavior

A full theory of how moral judgment develops is many years off, but even the present, partial theories make it clear that moral judgments do not lead directly to moral behaviors. We can all bring to mind things that we have done despite knowing they were wrong, and extensive evidence supports this intuitive sense that we do not always act as we think we should (Tangney et al., 2007). Moral behaviors are determined by many other factors besides moral reasoning and judgment. In this section, we will focus on the development of moral behavior in its own right and also consider its relationship to moral thought.

We start by considering whether individuals typically behave consistently in moral or immoral ways across situations. This discussion leads to a consideration of the extent to which moral judgments predict moral behaviors. We then consider some temperament and personality factors important to moral development and reflect how they relate to the emergence of antisocial and prosocial behavior. This discussion raises controversial questions about whether individual differences in morality may have biological bases. We then consider social influences on moral development, including the role of parents in the early development of conscience, and both the punishment and modeling approaches to guiding moral development.

Consistency of Moral Behavior

If a child cheats regularly in the classroom, does he also cheat on the playground? If so, at least the behavior is potentially consistent with an admittedly nonstandard set of beliefs about what is right. But if classroom cheaters are rarely also playground cheaters, this discrepancy suggests a weaker link between moral judgment and action and a significant influence of situational factors.

In the early twentieth century, researchers studying cheating in the classroom and cheating on the playground were surprised to find that cheating in one context did not seem to indicate cheating in another (Hartshorne & May, 1928; Hartshorne et al., 1930). Children who were scrupulous about classroom work might be the worst offenders at recess, and vice versa (see Figure 12.8). It appeared that, given the right range of contexts, almost any child could be observed to cheat, but hardly anyone cheated consistently in all situations. In addition, when these children were asked about right and wrong behaviors, they usually disapproved of the same acts, even as they violated these judgments in their actions.

This classic study had two crucial implications: (1) it ruled out simple accounts of moral development that linked moral judgments directly to moral actions, and (2) it supported the theory that all personality traits (including those related to moral choices) are situation specific. Although later reanalyses of Hartshorne and May's data suggested more consistency than originally reported—especially when social conventions were distinguished from moral principles (Grusec & Lytton, 1988)—the general conclusion of some moral inconsistency for individuals across situations has endured. One scholar has argued that it is misleading to describe someone as brave or caring in general and that it makes much more sense to describe a person as brave in certain circumstances (such as when a close friend is being threatened by someone with a gun) or caring in specific contexts (such as when seeing someone in pain; Doris, 2002). In a different situation, that same person may not appear to be either brave or caring. A particular type of person might well show a strong tendency to behave in a particular way in a certain well-described set of situations, but would not always behave in this way and would not show a completely consistent moral character across all situations (Funder, 2006).

Another difficulty in predicting actions from judgments is that several different patterns of judgments may lead to the same actions. This is especially evident in Kohlberg's system, in which several different levels of moral reasoning can lead to each of the two possible choices in a moral dilemma. A study of one of the first campus political actions of the turbulent 1960s, the Berkeley Free Speech Movement, revealed this slippage between levels of reasoning and action among students confronted with a real-life moral dilemma (Haan et al., 1968). In 1964, the

A

B

FIGURE 12.8 **Consistency of cheating.** A classic study by Hartshorne and May (1928) suggested that children who cheat in the classroom **(A)** are not necessarily those who cheat on the playground **(B)**.

university administration became unhappy that students were distributing leftist political pamphlets on-campus, and it attempted to ban these materials, claiming that the tables set up to distribute them were slowing campus traffic. In response, the students conducted a traffic flow study documenting no such problems. When the administration did not back down, the incensed students insisted that their civil rights had been violated and eventually held a sit-in at one of the university buildings—a highly provocative act in which participants risked not only their academic standing but their future careers (see Figure 12.9).

Was it possible to predict who engaged in the sit-in based on their stages of moral reasoning? Haan and her colleagues assessed many of the demonstrators, using Kohlberg's moral dilemmas to determine their levels of moral reasoning. We might expect that only students at the highest levels would have engaged in an action that would put them at such risk solely on the basis of a relatively abstract principle such as free speech. In fact, students at several levels of moral reasoning were well represented. Although there were proportionally more protesters at Kohlberg's two highest levels of moral reasoning (Stages 5 and 6) than in the student body at large, there were also some protesters who were at Stage 2. Even as some students were demonstrating as a way of honoring principles, others were doing so apparently for purely hedonistic reasons. These students saw the sit-in as great fun, and their enjoyment outweighed the risks.

Q: Why might it be problematic to use someone's tested level of moral reasoning to predict his moral behavior?

Thus, many decisions and actions can be justified at various levels of moral reasoning or in terms of several different moral belief systems, making it quite difficult to use beliefs to predict behaviors (Keniston, 1970). People who consciously want their moral beliefs to be consistent with their actions may show more consistency (Blasi, 1980), but even this desire does not always result in consistency. Predicting moral behavior from beliefs may also be possible in studies that set up situations in which certain forms of

FIGURE 12.9 **Moral judgments and moral actions.** Although students who participated in the Free Speech Movement on the Berkeley campus in the 1960s were more likely to show higher levels of moral reasoning on Kohlberg's stages, there were still many other protesters from lower stages and many who did not participate from higher stages, revealing that there is no simple mapping from levels of moral reasoning to kinds of moral behaviors.

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

Moral Dumbfounding: Judgment or Intuition?

The idea that moral intuitions might be rooted in emotions is an old one, going back at least as far as the eighteenth century. Recently, researchers have proposed a new view of the role that emotions play in moral thought, spurred by the phenomenon of **moral dumbfounding**. This term refers to the finding that for some moral situations, people have strong convictions about what is right and wrong but are unable to explain why. The phenomenon of moral dumbfounding builds on an apparent disconnect between having strong "gut feelings" about what is right and being able to justify those feelings with higher-order reasoning. The phenomenon does not exist for all moral situations, only for certain ones that most people immediately consider wrong, although they cannot explain why.

In many cases, moral dumbfounding reactions fit within an evolutionary psychology perspective. One such scenario describes an adult brother and sister who have consensual sex (Haidt, 2003). The scenario painstakingly describes how the brother and sister decided to do it only once, used contraceptives, and had no adverse emotional reactions. The vast majority of adults find the scenario shocking and instantly condemn it as wrong. Yet, when asked to explain why they think it is wrong, most adults either give incorrect reasons (for example, "the couple might have a child with genetic defects," even though they know the couple used contraceptives) or say they don't know why. People judge quite a large number of scenarios in this way. For example, even if they are not religious, people think it is wrong to use sacred articles to, say, clean out a toilet bowl, whether or not anyone else even knows about it, and yet they are "dumbfounded" when asked to explain why (Haidt & Bjorklund, 2008; Haidt & Joseph, 2004).

Moral judgments of this sort may be like judgments of aesthetics. Most people who find a sunset beautiful would be hard pressed to explain why it is more beautiful than any other. People seem to perceive the beauty directly. Similarly, some moral intuitions may be triggered by emotional reactions rather than being a result of deliberative rational thought. These cases that rely on gut feelings about what is right might be quite distinct from cases that require careful reasoning.

One way researchers have studied these kinds of situations is by presenting participants with two moral situations, only one of which draws on emotion-based intuitions. For example, imagine that you are at a trolley stop, and you see that a runaway trolley is about to kill five people on the track. You can pull a switch that will send the trolley onto a different track on which there is just one person who will be killed (see Figure 12.10). Is it right to throw the switch? Most people say it is, and they give thoughtful explanations about sacrificing one person to save five people. Now consider a second situation that is similar to the first, except that instead of throwing a switch, you can shove a large, curly-haired man with glasses from a footbridge onto the tracks in front of the trolley, knowing that sacrificing this one man's life will save the other five people, as the large man's body will stop the trolley before it reaches the other five people.

Most people find the second action unacceptable. But what is the difference? The first scenario describes an **impersonal moral situation**, one that is abstract and does not directly involve specific individuals. In this case, it is relatively easy to distance yourself from the situation and consider the tradeoffs involved in either throwing the switch or not. The second scenario describes a **personal moral situation** because it involves the individual in the situation in a direct, immediate way (Greene et al., 2001; Singer, 2005). Thus, in the switch-throwing (impersonal) case, it is relatively easy to distance yourself from the situation and consider the tradeoffs in abstract terms. In the shoving (personal) case, it is impossible not to encode the effects of this action on a specific person (which is why the description includes personal characteristics), and it is difficult not to be horrified at the thought of harming an innocent person.

Moral intuitions in impersonal versus personal situations appear to show different patterns of activation in the brain (Cushman et al., 2010). In fMRI studies of increased blood flow in brain regions that occurs while engaging in judgments about the two kinds of situations, different sets of brain regions become activated; for example, areas associated with emotional processing are significantly more activated in the personal moral situations than in the impersonal moral situations (Greene et al., 2001, 2004). In addition, people who suffer brain damage to the prefrontal cortex, a key region associated with personal moral intuitions, tend to make "utilitarian" moral judgments in which they treat both trolley scenarios as a simple weighting of the total number of lives saved (Greene, 2007; Koenigs et al., 2007; Young & Koenigs, 2007).

Moral dumbfounding arises from powerful emotions; there is an immediate sense of knowing what is right and wrong without reflection, based on a link between an emotion and a moral evaluation (Dwyer, 2009). The **social intuitionist model** of moral judgment suggests that in these cases, emotions like anger or contempt can be triggered automatically by perceived violations of norms and rights. Thus, people can have moral intuitions about a scenario without considering abstract moral principles (Haidt, 2001; Haidt & Joseph, 2004).

In this view, violations of the community's ethical norms can provoke contempt, violations of individual rights can provoke anger, and violations of sacred relations can provoke disgust (Rozin et al., 1999). According to the social intuitionist view, critical cultural experiences during late childhood affect the ways that these basic moral emotions become associated with particular situations. Thus, people in different cultures will sometimes have different moral reactions to the same situation. More specifically, the theory holds that children are especially sensitive to the way that expressions of anger, disgust, or contempt correlate with moral transgressions (of social norms, individual rights, or sacred relations) in their own cultures. Cultural psychologist Jonathan Haidt (2001) has suggested that there may be a sensitive period in late childhood during which time culture helps form links between basic emotions and certain kinds of culturally specific situations. Early moral emotions may also help spur the development of moral reasoning in the more cognitive realm. Thus, children who suffer brain lesions in a region critically associated with personal moral thought (which is often emotion linked) tend not to progress as far in terms of Kohlberg's stages (Young & Koenigs, 2007).

One criticism of the social intuitionist model of moral development is that it may overemphasize the role of emotions at the expense of cognition. As noted earlier, people can reason in advance extensively about a type of moral situation, building up cognitive schemas that can guide rapid moral judgments when the situation arises. Similarly, the effects of culture may be mediated by rich cognitive structures that lead to highly automatic and reflexive modes of responding, even if it took considerable time to build up those routines. Even if the moment of making a moral judgment does not involve extensive explicit reasoning, this kind of thought over the course of past experiences may have laid the groundwork for rapid responses (Pizarro & Bloom, 2003). In addition, the phenomenon of feeling certain but being unable to explain why may not be unique to moral dumbfounding. People who are confident that they know how common everyday items work are often shown to be clueless (Rozenblit & Keil, 2002; see Chapter 10). Even with these concerns, however, the social intuitionist approach is charting an important new direction for moral development research by challenging researchers to consider precisely why and when emotional reactions rather than explicit reasoning guide moral judgments.

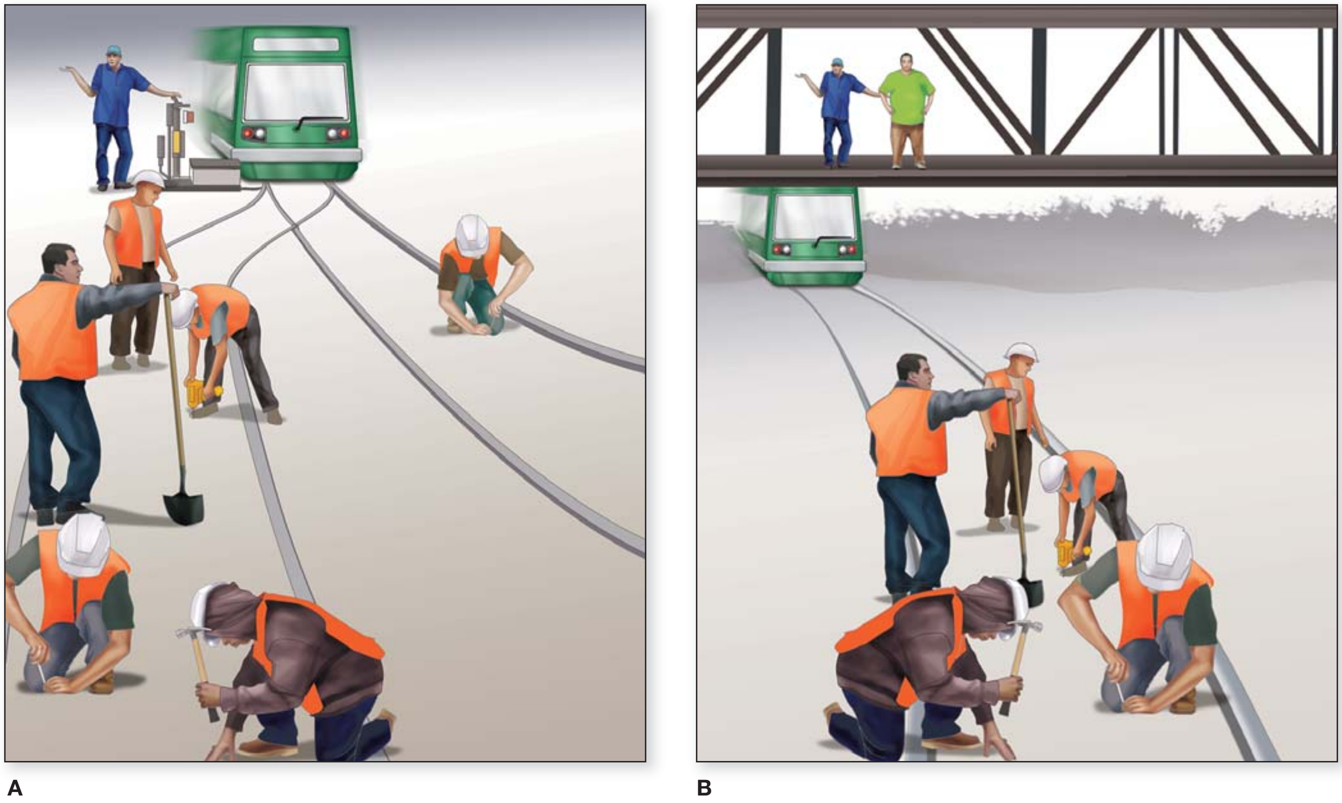

FIGURE 12.10 Moral dumbfounding. (A) In the first scenario, there is a runaway trolley and five people are on one track and one person is on another track. Participants are asked if they would throw a switch that would shift the trolley from the track on which five people would be killed to the track on which one person would be killed. **(B)** In the second scenario, participants are asked if they would push one person onto the track to save the five people on the track.

reasoning are likely to suggest specific kinds of responses. For example, in situations where respected authority figures urge participants to do something morally questionable, participants whose moral reasoning is more authority based are more likely to go along with the authority. You may have read about social psychologist Stanley Milgram's study of obedience, in which subjects were urged to give increasingly powerful shocks to a "learner" each time he made a mistake on an experimental task (Milgram, 1963). Although the learner was actually a confederate of the experimenter and no real shocks were administered, the participants in Milgram's study did not know this, and the majority of them followed the experimenter's instructions, despite believing that they were causing the learner great pain. In another version of this classic study, Kohlberg and Candee (1984) found that 75 percent of the people who were at Stage 6 in Kohlberg's stages of moral reasoning refused to increase the amount of shock as the experimenter ordered, whereas only 13 percent of subjects at lower levels of moral reasoning refused. This finding has been interpreted as showing that Stage 6 people are less inclined to make moral judgments and take action based on appeals to authorities. They may feel less obligated to follow the instructions of authorities, or they may not view the experimenters as being authoritative, or they may not be as intimidated in general by the views of others.

The conclusion from these sorts of studies is that simply examining someone's beliefs or judgments about what behavior is right in a given situation is not a reliable way to predict behavior. It is often possible to explain the reasons for a behavior after the fact, but predicting behavior is much more difficult. In addition, there is no evidence that the weak link between beliefs and behavior is more (or less) straightforward among young children (Hardy & Carlo, 2011; Kang & Glassman, 2010; Walker, 2004). Nonetheless, this complexity does not indicate that beliefs are completely separate from behaviors. The links between them are likely to be both intricate and powerful, but they are hard to predict because so many influences affect behavior and because many situations are ambiguous.

These features of moral behavior in older children and adults raise a central question about development: Do younger children tend to show more behaviors that are considered immoral than older children and adults do? Do children gradually engage in more morally appropriate behaviors as they mature? To be sure, younger children may have more difficulties resisting some temptations, may not always be as sensitive to how their actions influence others, and may be less prone to shame and guilt. But for all these differences, their behaviors do not show a general trend toward becoming increasingly moral.

Antisocial and Prosocial Behavior

To find out whether different types of moral and immoral behaviors show developmental patterns, we first need a way of classifying such behaviors. A good classification system should clearly distinguish moral acts from immoral ones, and it should include subtypes within the category of immoral and moral acts to help distinguish which ones, if any, show developmental changes. Any such classification of moral and immoral behaviors is difficult. It raises problems concerning differences in morality across cultures, as well as difficulties in evaluating actions alone without full information about intentions.

Despite these complexities, research in moral development has focused on two broad categories of behavior: prosocial behavior and antisocial behavior. **Prosocial behavior**, or altruism, normally refers to actions performed for the benefit of others and at some cost to the person performing the action. **Antisocial behavior** consists of acts that harm another individual or a group. It includes not only physical violence, but also verbal assaults and attacks on society and norms, such as cheating and stealing. In considering antisocial behavior, we will sometimes use the term *aggression* to describe hostile acts that are detrimental to others, rather than referring to the personality trait of an aggressive personality. This distinction is important because some people may be seen as having highly aggressive personalities but not as behaving immorally.

Q: Describe several different examples of prosocial and antisocial behaviors.

Antisocial Behavior There are no obvious developmental trends in the tendency to cheat. A surprising number (some say more than 50 percent) of elementary school children cheat at some time in their grade school days (see Figure 12.11). Interestingly, the incidence does not seem to drop as they grow older. It continues in secondary school and beyond (Davis et al., 1992; Evans & Craig, 1990; Houser, 1978; Jensen et al., 2002). Some estimates suggest that as many as 75 percent of college students cheat at one point or another. Moreover, cheating does not stop at the end of college. Estimates of people who cheat to some degree on their income tax returns run very high. And there are many people who do not tell a cashier when they are mistakenly undercharged. In short, there is no evidence that people cheat less as they get older.

Similarly, there is no evidence of developmental trends for stealing, lying, and disloyalty. These behaviors may take a different form with age, as transgressions become increasingly sophisticated and subtle. Still, it is not clear

FIGURE 12.11 Cheating by children in school. As shown in this photo of rural schoolchildren in Tibet, cheating occurs throughout the world. Although cheating may become more subtle and sophisticated, there is no evidence that cheating becomes less prevalent with increasing age.

that once a child has reached toddlerhood, there is a developmental change in the prevalence of any of these types of immoral acts. Of course, it can be difficult to compare and measure the immoral behavior of people at different ages. But young children are typically much less capable than adults of inflicting harm, regardless of their intentions, and adults are often much more capable of concealing antisocial behaviors or casting blame on others. Once those factors are accounted for, it is much more difficult to know whether the rates of *purposeful* antisocial behaviors change with age.

Most children do become better able to control their impulses and delay gratification of their immediate desires as they grow older. Hence, moral transgressions related to such difficulties often occur less often with age. Nonetheless, many transgressions are not based on an inability to delay gratification.

Prosocial Behavior The same lack of a clear developmental trend occurs in analyses of cooperation and competition. Although many Western cultures encourage competition, experimenters studying cooperation and competition generally consider cooperative behavior more morally desirable and reward cooperative behavior much more strongly. Figure 12.12 shows a game that has been used for studying cooperation and competition among children in many cultures. First, a marble is put in a container, which is in the middle of a table. Two children sit on opposite sides of the table, and each one takes one of the strings attached to the sides of the container. The object of the game is to pull on the string to move the container close enough to reach in and get the marble. The children are told that they will receive a reward for every marble each of them gets (Kagan & Madsen, 1972). Every time one child gets a marble, the container is put back in the middle of the table, and a new marble is put in it. The container is held together by magnets, and if both children pull hard on the strings, the container will come apart and the marble will roll away, so that neither child will get it. The only way to get the marble is to agree to cooperate by taking turns, such that first one child pulls the container close enough to take out the marble while the other child holds the string lightly and does not pull, and then the other child pulls the container and takes out the marble.

In practice, many children never seem to reach a level of mutual trust that allows them to cooperate by taking turns, and therefore neither wins any marbles. Rather than finding a general developmental trend of increasing cooperation in all children, this research points to individual differences, with some children being much more cooperative than others. These findings have held up across many kinds of assessments of cooperation and competition, ranging from observational studies of free play to more structured games and scenarios. Research in this area also shows strong

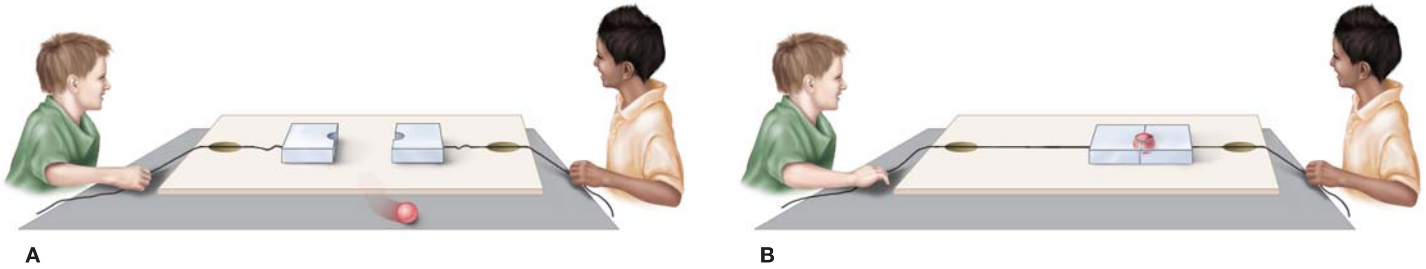

FIGURE 12.12 Cooperation versus competition. Shown here is an apparatus used to measure cooperation and competition among children. The goal is for each child to retrieve a marble from within the container. Competitive participants simply pull on the strings, causing the breakup of the container (which is held together by magnets), and thereby causing the marble to roll away, so that neither child gets the marble. Cooperative participants agree to let each other get a marble on successive terms. Adapted from Madsen & Connor (1973).

cross-cultural differences. For example, in one classic study, children in a small Mexican town cooperated considerably more on the marble task than did children from an American town (Madsen, 1971).

Q: Describe how cooperation and competition might be measured in two children.

Some studies have found gradual developmental increases in prosocial behaviors such as sharing and helping (Eisenberg & Mussen, 1989; Eisenberg et al., 2006). But it can be difficult to distinguish between a child's emerging grasp of socially approved behaviors (such as holding a door open for others) and an increase in a genuine desire to engage in more altruistic behaviors. Recent studies suggest, however, that if the situation is set up appropriately, very young children can be strikingly altruistic and prosocial, both in

SCIENTIFIC METHOD: **Instrumental Helping in Toddlers**

Hypothesis:

When a situation clearly shows that a person is in need of help to achieve a goal, even young toddlers will behave altruistically.

Method:

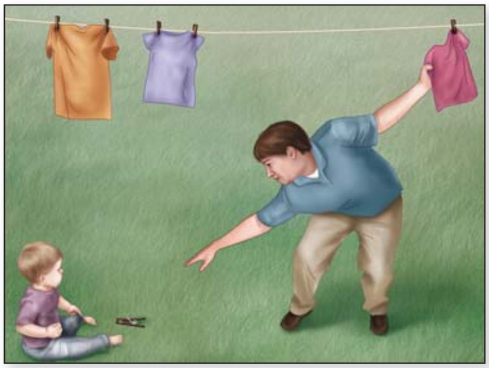
1. Twenty-four 14-month-old toddlers participated in the experiment.
2. All the children saw an experimenter (1) drop a clothespin while hanging up clothes and then try to retrieve it, (2) drop a marker while making a drawing and then try to retrieve it, and (3) try to pick up paper balls with tongs when the balls were out of reach for the experimenter but not for the child.
3. In a control condition, the experimenter intentionally threw away the clothespin/marker or did not try to move the paper balls to a new spot.
4. The researchers recorded the incidence of instrumental helping by the toddlers.

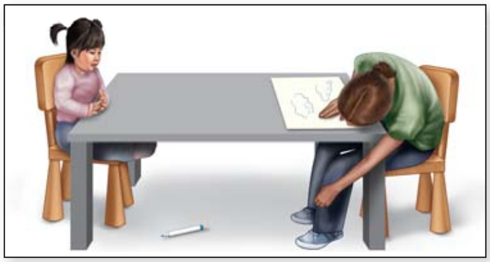
Results:

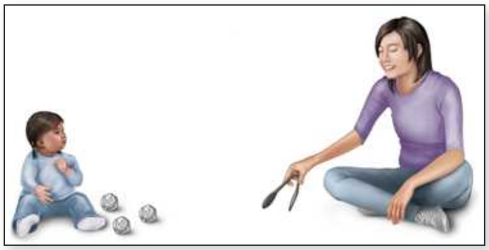
In all three tasks, but especially the paper ball task, toddlers helped more in the experimental condition.

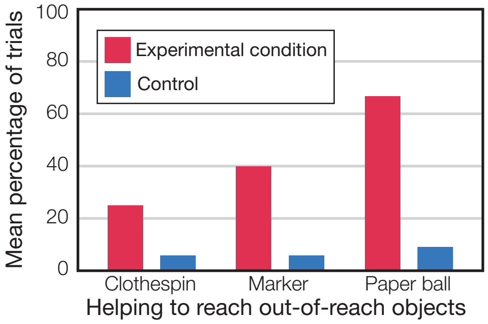
Conclusion:

In tasks that involve instrumental helping of another person to achieve a goal, very young children will altruistically offer assistance at no benefit to themselves.





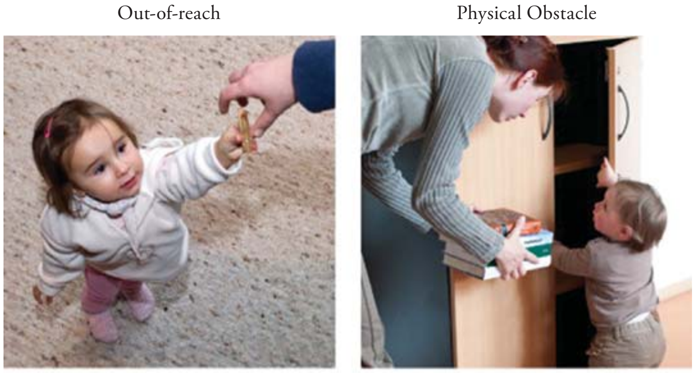




Source study: Warneken & Tomasello (2007).

terms of helping others and in terms of wanting to be fair about the distribution of resources (Shaw & Olson, 2012; Warneken et al., 2011). One line of work depicts adults struggling to do some task in which assistance would help them greatly (such as trying to open a cabinet while carrying several things or trying to obtain an out-of-reach object; see Scientific Method box). Even infants as young as 14 months old will spontaneously act to help when they see someone in need (Warneken & Tomasello, 2006, 2007). Younger children may have difficulty inferring complex goals and coordinating helping actions, but when the task is as simple as providing objects that another person is trying to reach, even 14-month-olds do offer to help when there is no obvious benefit to themselves or any expected reward from the person they are helping.

This form of prosocial behavior is called **instrumental helping**. It involves perceiving someone who is unable to achieve a goal and acting altruistically to help that person, even when there are no obvious benefits to the helper (see Figure 12.13). Thus, even when 18-month-olds are presented with physical obstacles to climb over to help another, they readily do so, suggesting a desire to act even at considerable personal cost (Warneken & Tomasello, 2009a). This is different from prosocial behavior based on sharing or comforting, both of which may appear somewhat later in development.

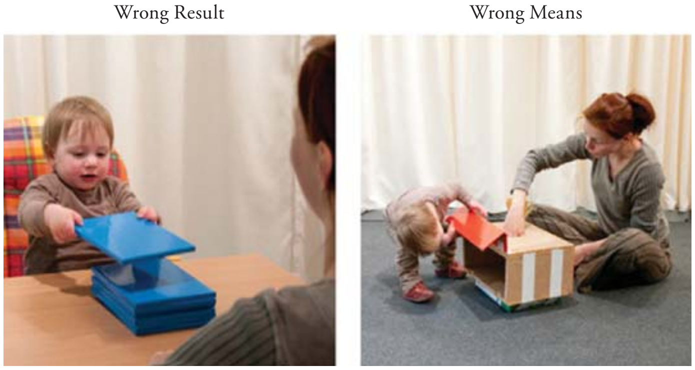


Out-of-reach

Physical Obstacle

A person accidentally drops an object on the floor and unsuccessfully reaches for it.

A person wants to put a pile of books into a cabinet, but she cannot open the closed doors because her hands are full.



Wrong Result

Wrong Means

A book slips from a stack as a person attempts to place it on top of the stack.

An object drops through a hole into a box and the person unsuccessfully tries to grasp it through the small hole, ignorant of a flap on the side of the box.

FIGURE 12.13 Early altruism. Children who are at least 18 months old will help adult strangers, even when there is no obvious benefit or reward for helping. From Warneken & Tomasello (2009b).

Slightly older children will help even when it costs them the opportunity to play with extremely attractive toys. These children are clearly not motivated by rewards; indeed, they will help just as often when the person who needs the help does not reward them as when the person does. In fact, in some cases, external rewards can actually reduce the desire to help in the future for reasons discussed more extensively in Chapter 13.

The evolutionary roots of instrumental helping seem quite old. Chimpanzees, whose common ancestors with humans go back several million years, will help caregivers who are trying to reach for an object and will do so in situations where no rewards are present (Warneken & Tomasello 2009a). Chimpanzees may not show helping in as wide a range of situations as young humans, but there is clearly a common drive to help others in ways that reflect true altruism.

Recent research has also shown that young children can be quite sophisticated and prosocial in their sharing behaviors as well. Although children may not seem to engage in much sharing until around 5 or 6 years of age, some situations will elicit genuine sharing at considerably earlier ages. For example, when children engage in collaborative efforts, even 3-year-olds will share fairly in the fruits of those efforts (Warneken et al., 2011). They will also adjust their allocations so as to provide more resources to those who work more productively (Kanngiesser & Warneken, 2012).

One theory of the development of altruistic helping is that younger children are more indiscriminately helpful in cases where they clearly perceive a person in need of help. As they get older, however, they start to be more selective in whom they choose to help, and they become more influenced by such factors as whether they see the individual as belonging to the same social group as themselves and whether they see the person as worthy of help (Warneken & Tomasello, 2009b). Because of their lack of discrimination, younger children may actually be more altruistic than older children.

Yet, in other contexts, young children may be less altruistic, at least in situations where their lack of fairness is unlikely to be detected by others. Thus, young children who are asked to allocate resources for another child who is not yet present and who will not know of their actions will often allocate more resources to themselves even when older children and adults would think it only fair to allocate them equally (Sheskin, 2013). Other studies show that between roughly 6 and 11 years of age, children want to appear to be fair in allocating resources when others will witness the allocation, but will still be more unfair when it won't be detected (Shaw et al., 2013). More generally, when considerable rewards are at stake and a salient audience is not present, young children may have more difficulty behaving fairly and prosocially and may be less generous (Leimgruber et al., 2012). The cases of spontaneous helping by much younger children are not an exception to this pattern because there is no competing strong reward. Empathy for others who are in trouble may be very early emerging, but fair allocation of rewards may be much more situationally sensitive and often difficult for young children.

Above and beyond any possible development patterns, there are huge differences among individuals. Even if people are not fully consistent across situations, individuals still show clear differences in the way they act in moral situations. Perhaps only 1 person out of 1,000 would dive into the sea to save a drowning stranger 100 yards away (see Figure 12.14); only a handful of people would walk past an old lady who has fallen in the street without offering help; only a small number of people would try to verbally and physically intimidate others to gain material resources.

These differences across individuals raise the compelling question of why some people act in more morally appropriate ways than others. Situational factors can be enormously compelling, but how can we explain the clear individual differences that exist over and above situational influences? We have already seen that differences in moral judgments are fairly poor predictors of differences in moral behavior, so what are other factors that might cause such individual differences? At the broadest level, two other factors lead to individual differences in moral behavior—and by this point, they will be familiar as sources of individual differences in other areas of development as well: (1) temperament and personality, and (2) differences in social influences. It is in these two areas that most of the research on prosocial and antisocial behavior has occurred. This research tends to ask why some individuals show more (or less) of a behavior than do others, rather than seeking universal patterns of moral development.

FIGURE 12.14 **Altruistic behavior.** Prosocial reasoning about altruism—helping others at a possible expense to the helper (here a person is jumping into the water to save strangers who are drowning)—may include stages in which there is a concern with self-interest, a desire to seek the approval of others, and an appeal to internalized principles. Researchers ask if reasoning about altruism should be considered a distinct domain with its own trajectory.

Temperament, Personality, and Moral Behavior

Most researchers who investigate individual differences in moral behavior do not consider some children to have inherently better or worse moral judgment than others. They do, however, ask whether particular psychological mechanisms could make some people more likely than others to commit immoral acts. These mechanisms could range from differences in impulse control to the degree of empathy someone experiences. Even when the right thing to do is clear, some people might find it easier than others to resist temptation or to delay gratification. Similarly, people who have difficulty empathizing with another's pain or need would likely have trouble using the Golden Rule or care-based forms of moral reasoning. It is critical to keep in mind the difference between psychological processes that often lead to moral (or immoral) actions and the ability to make moral judgments.

Q: How are psychological processes that might help foster immoral behaviors different from psychological processes that underlie moral judgments?

Self-Regulation One of the most frequently discussed sets of processes associated with prosocial and antisocial behavior is **self-regulation**, the ability to control our impulses by managing our emotional states and our reactions to others and to situations and to delay gratification of desires rather than always acting on them immediately (see Figure 12.15). An impulsive person with poor self-regulation will not necessarily engage in immoral behaviors, but he may engage in actions that are considered morally inappropriate since they often spring from an inability to suppress a desire or impulse.

Studies examining differences in immoral behavior more often focus on adults than on how this kind of behavior develops. One reason for this is that immoral behaviors are difficult to document until later in life, when infractions such as school suspensions and criminal convictions make this kind of behavior easier to identify and measure. For that reason, the study of self-regulation in adults is closely con-

FIGURE 12.15 **Self-regulation.** A lack of self-regulation—such as drawing on the wall of a formal living room—can be interpreted as immoral behavior if the child is thought to be old enough to know better.

nected to morality, while these topics have more often been studied separately in children. We will discuss the development of self-regulation in more depth in Chapter 13, which concerns the child's awareness of the self and others. Here we discuss self-regulation more narrowly in the context of its links to the study of moral behavior.

Self-regulation in the broadest sense is concerned with modulating our emotions in ways that help us accomplish a goal (Eisenberg et al., 2004). It can often involve inhibiting an impulse, but it can also involve initiating an emotional state, such as consciously working up our courage to do a difficult act. In all its forms, this kind of effortful control of behavior is more difficult for young children, perhaps because the ability to self-regulate is heavily related to the maturation of the prefrontal cortex.

Children with poor self-regulation or low impulse control may be unable to wait long enough before they act to consider the consequences of their actions. Thus, they may act on their impulses before they realize that their actions may hurt others or violate social rules (Dunn & Hughes, 2001). Poor impulse control can also lead to a tendency to give in to temptation, even while knowing that it is better to do otherwise. On the other hand, when a child has better impulse control, even a small delay before doing something questionable may provide the child with enough time for reason to exert an influence.

Self-regulation is also related to the ability to delay gratification. **Delay of gratification** simply refers to the ability to hold off engaging in an action that will bring a desired reward. Some individuals seem to need positive experiences immediately and are unable to wait for what they want. They might well choose to get a small reward for minimal sacrifice over the option of working longer at an unpleasant task to earn a much larger eventual reward. Despite the common assumption that antisocial children and adults have difficulty with impulse control and delay of gratification, few studies convincingly show a biological predisposition for such difficulties.

Personality variables also seem to influence the extent to which a particular environment leads to behavior problems. One analysis of very low income families asked which children in those families showed more **resilience—**that is, the ability to adjust or recover from adverse events or situations—in the harsh environment (Buckner et al., 2003). Children with higher levels of self-regulation, as measured by emotion management and executive functioning skills, were also more resilient. It should be noted, however, that these children also had more actively involved parents, raising the possibility that both parental effects and common, genetically driven temperamental components contributed to their higher levels of self-regulation and resilience.

Problems with self-regulation and delay of gratification have been suggested as a partial cause of extreme antisocial behaviors that can lead to criminality. There have been repeated suggestions that criminality is higher among individuals who are more closely related genetically (Eysenck, 1996; Gabrielli & Mednick, 1983; Wilson & Herrnstein, 1985). Several studies have found higher concordance rates among MZ twins than among DZ twins, but these findings on their own cannot easily rule out the fact that MZ twins also experience more similar environments (Joseph, 2001). More compelling are adoption studies in which environmental and genetic differences are more neatly separated. In one adoption study in Denmark, adopted children whose genetic fathers had criminal records were twice as likely to have criminal records as were adopted children whose genetic fathers did not have criminal records (Hutchings & Mednick, 1977; Mednick et al., 1984). These findings have been criticized, however, on the grounds that the placement of adopted children is not random, which means that environment as well as genetic background could be influencing criminality (Joseph, 2001). Nonetheless, the research in this area tends to support a partial genetic basis for individual differences in antisocial behavior (Rhee & Waldman, 2002; Viding, 2004).

In addition to being related to self-regulation, genetic factors may also help make a child especially resilient to environmental stressors (such as child neglect) or especially vulnerable to those stressors. Thus, the strongest genetic influences are seen in particular kinds of environments and their interactions with particular alleles (Moffit, 2005). Moreover, it seems that genetic factors are more likely to influence the emergence of physical aggression than **social aggression**, which includes such behaviors as malicious teasing, social exclusion from a group, and humiliation (Brendgen et al., 2005).

Early antisocial behavior also tends to predict similar later behaviors. One way this connection has been documented is that children with conduct disorders are more likely to engage in criminal behavior as adults. Children who are diagnosed with a **conduct disorder** regularly transgress in ways that impinge on others' rights or in ways that violate social norms. In most cases, children who routinely steal, bully others, or cheat would qualify for this diagnosis, as would those who show a callous insensitivity in social interactions (Frick et al., 2003; Lahey et al., 2003). Children who consistently show these behaviors tend to exhibit them for extended periods, well into adulthood. As adults, they are more likely to be physically abusive toward both intimates and others. They are also more likely to violate the law and become criminals (Kazdin, 1995; Lahey et al., 2003; Loeber, 1996; Robins & Rutter, 1990; Zoccolillo et al., 1992).

The strong link between childhood conduct disorders and adult rates of antisocial and criminal behavior is not necessarily evidence of a temperamental or personality basis for antisocial behavior, however, since environmental influences are constantly at work as well. But the consistency that individuals' antisocial behavior patterns often show over much of the lifespan, combined with such traits as emotional insensitivity, does make it somewhat more plausible that underlying psychological differences may put some children more at risk for such behaviors.

In addition, theories about the genetic bases of more extreme immoral behavior, such as crime, may not fully apply to people who are prone to more moderate or mundane immoral actions. Most of the available statistics on conduct disorders and their links to adult behaviors examine only one extreme end of the continuum between moral and immoral behavior. But only a very small percentage of children are diagnosed with conduct disorders, and an even smaller percentage of them commit crimes as adults.

At present, many researchers believe that less extreme cases of antisocial behavior involve the same processes as cases of conduct disorder and criminality, but to lesser extents. Chapter 16, which deals with childhood psychopathology, discusses the dangers of assuming continuity between behavior associated with psychopathology and similar behaviors that are more common and less detrimental. Moreover, as we will see, genetic influences on criminality may extend far beyond the processes of emotional regulation and delay of gratification.

Arousal Level and Positive Emotionality Most people have a similar range of typical arousal levels. This means that they are typically alert and moderately reactive to normal stimuli. Arousal levels have been linked to moral behaviors on the assumption that they influence emotional reactions to stimuli and situations. Unusually low ranges of arousal have been of special interest. The notion of underarousal is widely invoked in explanations of adult criminality. For psychopaths, who feel neither empathy nor remorse, the arousal problem is largely emotional (see Chapter 16). Because they do not feel normal levels of anxiety about committing transgressions, they cannot learn from negative emotional feedback (Eysenck, 1964). For individuals with ADHD, the arousal problem is considered to be more attentional, leading to a decreased ability to maintain attention and to track what happens in their environment. This problem might include difficulty tracking various clues that an action is likely to be considered inappropriate or upsetting. Developmentally, each of these arousal deficits can become especially evident when parents and society try to instill a system of morality. If a child is emotionally underaroused, parents will have greater difficulty teaching moral lessons or instilling feelings of guilt about transgressions. If a child is attentionally underaroused, parents will have trouble ensuring that the child listens to moral explanations and understands the reasons for not engaging in certain behaviors. In addition, underarousal may be related to an inability to feel empathy, a correlation found in children as young as 2 years old (Young et al., 1999).

In addition to general arousal level, a child's temperament (see Chapter 7) is also related to prosocial behaviors. Studies have repeatedly found that children with sunnier dispositions—those who are temperamentally predisposed to show positive emotions—tend to have more frequent and stronger feelings of empathy than less upbeat children, and children who show more positive emotions are more likely to engage in prosocial behaviors (Eisenberg et al., 2000). One possible explanation for this link is that positive emotions may make it easier to think more about others' feelings rather than being more self-focused (see Figure 12.16). Research on the development of empathy has examined these issues and others in more detail.

Empathy We saw earlier that empathy plays an important role in Eisenberg's theory of the development of prosocial behavior. Her theory claims a close link between reasoning and behavior and emphasizes prosocial behaviors and empathy. Feelings of empathy are often thought to lead to appropriate prosocial behavior (Hoffman, 1990). Considering the wide range of individual differences in prosocial behavior, do some people simply have less capacity to feel empathy for others? Can someone with normal social and cognitive abilities nonetheless be unable to feel empathy? This question leads back to psychopathological popula-

FIGURE 12.16 Empathy. Children differ in the extent to which they feel empathy and act on those feelings, in this case comforting another child in distress. Young children who show high levels of empathy and empathy-motivated behaviors are more likely to show similar behaviors in later years.

tions, particularly psychopaths, who rarely feel intense emotions of any kind. In the case of empathy, this deficit leads to an inability to emotionally put themselves in another person's shoes. In addition, there is some evidence that genes contribute to differences in the ability to feel empathy (Frick et al., 2003; Zahn-Waxler et al., 2001). Such a genetic contribution may help explain why young children who show prosocial behaviors, such as sharing toys, are more likely to make substantial charitable contributions as adolescents or young adults (Eisenberg, 2005; Eisenberg et al., 1983, 1991, 2002). The strong, immediate empathy that leads a 3-year-old to share a favorite doll may, in a more mature form, lead her to make regular donations to a homeless shelter.

In their first year of life, children may share others' distress mostly as a form of imitation. Shortly thereafter, their imitation seems to become full-fledged empathy, leading children not only to feel another's distress but in some cases to try to alleviate it (Cole et al., 1992; Eisenberg, 2000; Meltzoff, 2002; Zahn-Waxler et al., 1992). Empathy in young children also enables them to engage in moral actions without having to rely on moral reasoning. Thus, just seeing someone else's distress may trigger a desire to comfort that person separate from forming a judgment about how that person has been treated. A strong sense of empathy alone, however, does not guarantee that a child will engage in a moral action, as other influences can also come into play. For example, a child might witness a classmate's humiliation in front of a large group and fully feel her classmate's pain but be unable to intervene because she is too shy to act in front of the group.

Of course, feeling empathy and acting on it can take many forms. There are different levels of empathy that correspond to different levels of cognitive, perceptual, and emotional complexity. For example, empathy-related phenomena across various species can range from simple agitation that an animal may feel when a member of its species is in pain, to imitation, to purposefully taking another's point of view (as do humans), to fully experiencing another's suffering (Preston & de Waal, 2002). In evolutionary terms, the ability for groups with shared genotypes to cooperate can provide members with a selective advantage, since this can make them more likely to survive and reproduce, making it more likely that they will pass on their genotype to a new generation. This logic may help explain why many organisms have developed behaviors that enable them to be sensitive to the emotional states of others (Sober & Wilson, 1998).

Similar to the notion that there are different degrees of empathy and that empathy-related behaviors can take many forms, psychologists often distinguish between emotional empathy and cognitive empathy (Losoya & Eisenberg, 2001). Experiencing **emotional empathy** involves witnessing another's emotional state and, in a relatively immediate and direct way, feeling the same emotion. It appears to be a more basic and earlier-emerging form of empathy. **Cognitive empathy**, which involves understanding and representing the emotional and mental points of view of others, requires social cognitive skills and the ability to take another's perspective. Cognitive empathy is often thought to develop later than emotional empathy and to be evolutionarily more recent. The finding that emotional empathy and cognitive empathy seem to activate different brain regions has led some researchers to suggest that people with autism have a deficit in cognitive empathy but not emotional empathy, while psychopaths may have the opposite deficit (Blair, 2005, 2008; Saxe, 2006; see Chapter 16). More broadly, fMRI studies of children suggest that emotional empathy appears early in development and involves activation of the amygdala and related regions and then later becomes integrated with more frontal cortical areas that involve more cognitive forms of empathy (Decety et al., 2011).

A third form of empathy, called **motor empathy**, is usually described as being elicited either as part of the process of pure physical imitation or by simply observing and feeling an action that we might be able to reproduce. As discussed in Chapter 4, it may be mediated by mirror neurons, which are the neurons in specific brain regions that fire either when a specific action is performed or when we see another person engaging in that action (Blair, 2005; Decety & Lamm, 2006). These three forms of empathy very often interact with each other. Thus, motor empathy may often trigger emotional empathy, and emotional empathy in turn requires at least some sense of cognitive empathy to understand how "the other" relates to the self (Losoya & Eisenberg, 2001).

Empathy seems to be closely linked to emotional regulation as well (Eisenberg, 2005; Eisenberg et al., 2006). If a child is overwhelmed by negative emotions triggered by another child's distress, that flood of emotions may lead the child to focus on his own feelings rather than on those of the other child. To recognize emotional states in others, children must be able to pull back and modulate their own emotions. Thus, children who are found to have higher levels of emotional regulation seem to feel more emotional and cognitive empathy for others. Across several studies that asked teachers and parents to rate elementary school students' emotional regulation skills, the children who were rated as having higher levels of emotional regulation were found to also be more likely to show feelings of empathy for others (Eisenberg, 2005).

Empathy is also influenced by the social context in which an individual is immersed (de Vignemont & Singer, 2006; Dovidio et al., 2006; Lanzetta & Englis, 1989). For example, in situations that promote cooperative efforts, people are prone to feel empathy toward others in their group. But in competitive situations, they may actually feel sadness at others' happiness and joy at others' misfortunes, a phenomenon that has been called *counterempathy* (Lanzetta & Englis, 1989). The classical notion of *schadenfreude*, or "pleasure from the misfortune of others," may well predominate in situations when the other person is construed as a rival. Developmentally, we can see how differences in children's cooperative and competitive tendencies could interact with aspects of the situation that promote either feelings of empathy or feelings of counterempathy. In some tasks, children show more joy in succeeding in a difficult task when another child does worse and more envy and antagonism in failing when another child does better. This version of *schadenfreude* is stronger in younger children (age 7) than in older children (age 13) and may be related to reduced sharing behavior in younger children (Steinbeis & Singer, 2013).

In summary, many factors related to temperament or personality can influence moral behavior, but they do not directly make a child behave morally or immorally. A child can be impulsive or emotionally volatile without showing a high incidence of immoral behaviors. Similarly, a child with great empathy for others may still not act on those feelings in prosocial ways especially in some competitive situations. Even when we examine the strongest links between a temperamental factor and a moral behavior, the influences of socialization and other environmental factors on behavior are potentially very large. We turn to those effects in the next section.

Social Influences on Moral Behavior

All children engage in inappropriate behaviors from time to time. Most children lie, cheat, or steal at least a few times during their childhood. Moreover, it seems that parents, peers, and society at large all influence children's tendencies to engage in antisocial and prosocial behaviors. In fact, the vast majority of research on moral development in children has asked how various social factors influence moral behavior. In this section, we will consider how such factors can influence both antisocial and prosocial behaviors; in essence, we will begin examining how children are socialized. In later chapters, we will more systematically consider how families (see Chapter 14) and the community at large (see Chapter 15) socialize children. Here we will focus specifically on the social influences on moral behaviors.

We would all like the next generation of children to be virtuous—to refrain from lying, cheating, stealing, and using physical and verbal aggression to intimidate and unfairly gain resources from others. Antisocial behaviors can be learned in several ways, and there are several ways to discourage such behaviors. Many of these types of social influences follow traditional theories of development.

A number of theories have set out to explain how social influences affect children's moral behavior. Learning theorists think in terms of positive and negative reinforcements, using rewards and punishment to change children's behavior (Gershoff, 2002; Parke, 2002; Parke & Asher, 1983; Parke & Walters, 1967). Another classic theory of socialization, which is known as modeling theory, argues that people will reproduce behaviors that they see others performing. Regarding the development of moral behavior, this theory argues that when children see adults acting in prosocial ways, they are likely to curb antisocial behavior and engage in prosocial behavior (Bandura, 1971; Bandura & Walters, 1963). Many contemporary approaches take a more cognitive perspective on these social influences, asking how parenting practices, among other influences, help to instill a conscience in the child. As we will see, these different approaches offer a set of tradeoffs, in which each approach partially explains how parents and society might help make a child behave more morally, but no single approach provides a comprehensive account.

Punishment and Learning Theories Learning theory accounts of moral development tended to focus on the effects that positive and negative reinforcements, delivered in various patterns, have on children's behavior. These theories tended to dominate the psychological literature

DEVELOPMENT AND SOCIAL POLICY

At What Age Should an Offender Be Treated as an Adult?

Several high-profile cases of prosecuting juveniles as adults have raised questions about the age at which children should be held morally responsible for their actions. No one would think that a 4-year-old who kills an older sibling with his parent's gun should be held as responsible as an adult, but what about an 11-year-old or a 14-year-old?

Consider the case of Nathaniel Abraham, who in 1997, at the age of 11, shot and killed a stranger with a .22 caliber rifle. Nathaniel, who was 13 at the time of his trial, was prosecuted in court as an adult. Many observers were shocked at the thought of a 13-year-old being treated as an adult, but the prosecutors insisted that Abraham was no ordinary 13-year-old (see Figure 12.17). At the time of the crime, he had a long history of problems with the police, many of them involving violence against others (Bradshaw, 1999). Convicted of second-degree murder, he avoided imprisonment in an adult facility only because the law grants judges the discretion of sentencing children younger than 14 to juvenile facilities.

FIGURE 12.17 Treating youthful offenders as adults. Nathaniel Abraham, shown here in court at age 13, was tried as an adult for murder. A recent surge of such trials in several countries raises profound questions about how scientific research on the moral development of children should be used to evaluate the appropriate age at which juveniles might be tried as adults.

How does research on the development of moral reasoning and moral behavior bear on the question of trying a 13-year-old killer as an adult? Despite the thousands of studies on moral development, the implications are unclear. Given the difficulties of demonstrating clear stages in the development of moral reasoning, it is not an easy matter to declare that children at a given age simply lack a certain level of moral reasoning. Moreover, even if it were possible to create a scale of moral maturity, it would be difficult to ensure that the courts applied it consistently to all offenders. We know that a fair number of adults show moral reasoning patterns that seem to be more common among children. Should those people, who are not necessarily mentally deficient, be held less responsible for their actions than other adults?

A second issue concerns whether the justice system should be more concerned with protecting the safety of others or with punishing wrongdoers. It would be possible to make the case that a child who has committed a violent crime is likely to commit other violent acts in the future, but this does not necessarily mean that the child should be punished as an adult. In fact, imprisoning the child with adult criminals, who may exert an even more antisocial influence on him, may increase (rather than diminish) the chance that he will commit future violent crimes when he is released from prison. Instead of putting the child in prison, another approach might be to find a way to monitor the child so as to minimize his risk to others without treating him like an adult offender in other respects.

At present, perhaps the most that developmental research can offer is evidence for the wide variety of ways in which moral reasoning and judgment develop. Even if there are no clear moral stages, the many documented developmental differences in such areas as emotional regulation, forms of empathy, and understanding of consequences all support arguments for treating children differently from adults in the criminal justice system (Whaley & Koenen, 2001). We all believe that young children differ from adults in their abilities to appreciate the consequences of their actions and to inhibit their impulses. Still, we need to better understand how these abilities emerge before developmental differences should be brought to bear on public policy decisions.

in the middle of the twentieth century and have become less prominent in recent decades. They examined the efficacy of punishment in instilling moral behavior in a child. Among their findings, learning theorists documented that it is not the severity of punishment alone that most clearly predicts internalization of moral values. Instead, many factors interact with the way the punishment is delivered. One of the strongest factors concerns the timing of the punishment.

Theories about the role of timing in delivering an effective punishment were inspired by pioneering studies of the effectiveness of punishment with dogs (Solomon, 1964; Solomon et al., 1968). Imagine an experiment in which a hungry beagle is led into a room that has two bowls of food: an attractive bowl of the tastiest, freshest dog food and a bowl of a clearly inferior dry product. An experimenter sits between the two bowls of food with a rolled-up newspaper (see Figure 12.18). Naturally, the beagle starts to approach the bowl of tastier food.

At this point, the situation breaks into two experimental conditions. In one condition, the beagle is punished with a swat of the newspaper as soon as he merely touches the fresher food with his nose. The dog is not punished for touching the inferior food, however, and eventually, he eats that food instead. In the second condition, the beagle is allowed to begin eating the preferred food before he is punished, and he is then restricted to eating the inferior food. If the dog is later led into the room that has both bowls of food, will he be more likely to continue to avoid the bowl with the tasty food and eat the dry food in the other bowl?

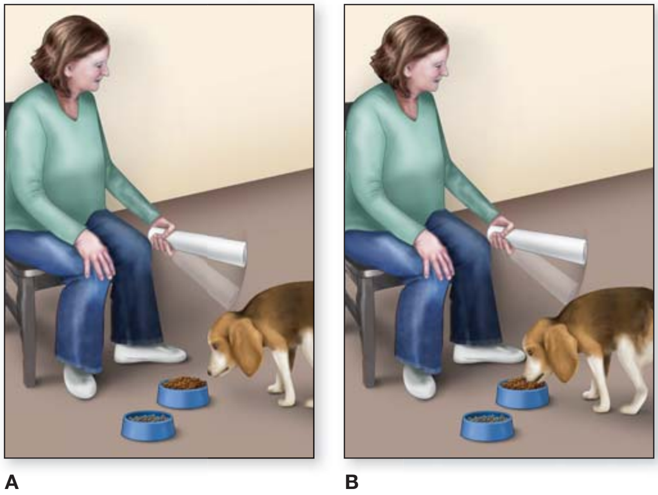


FIGURE 12.18 **Early and late punishment.** In a classic study with beagles, the experimenters either **(A)** punished the beagles immediately upon detecting their intent to eat a preferred food (early punishment), or **(B)** punished them as they were eating some of the desired food (late punishment). Although both groups of dogs learned to eat the inferior food in the immediate training task, the delay of punishment had a very different effect on later behavior. Adapted from Solomon et al. (1968).

It might seem that the punishment delivered after the dog began to eat would be more effective than a punishment delivered while the dog was merely initiating the action. In fact, punishment delivered early was much more effective. Beagles punished early continued to avoid the desired food, even when they were alone in the room with no experimenter present. They would enter the room, cast a seemingly forlorn look at the better food, and then unenthusiastically eat the inferior food. By contrast, beagles punished later would sneak over to the favored food and eat it rapidly and nervously, sometimes seeming to look apprehensively toward the door where the experimenter might appear. In short, punishing early seemed to cause a lasting avoidance of the superior food, whereas punishing late caused the dogs to be more furtive about eating the superior food.

Q: How does timing of punishment seem to interact with the internalization of a desired behavior?

Because a beagle's intelligence obviously differs markedly from that of a child, the punishment-induced inhibition is not thought to involve a cognitively rich sense of guilt. Instead, it is assumed that with early punishment, the dog is conditioned to have a negative arousal so early in the action that he changes his behavior. By contrast, if the negative arousal is conditioned after starting the behavior, it occurs too late to inhibit the behavior. Instead, late punishment often results in behavior that is focused on avoiding getting caught.

You might think that children, with their more sophisticated levels of thought, might not show the same pattern of responses to the timing of punishments. Yet, in a series of studies modeled closely after the Solomon studies with dogs, early punishment was shown to be much more effective for children as well (Parke, 1969; Parke & Walters, 1967). In this study, kindergartners were taken to a classroom where there was an appealing toy (such as a bright red truck) and an unattractive "toy" (such as some small drab toy dishes). Children in the early punishment condition were scolded for approaching the attractive toy, whereas children in the late punishment condition were rebuked only after they began playing with it. The children were then left alone in the room with the toys while the experimenters watched them covertly. Like the beagles, the children punished early reluctantly trudged over to the unattractive toy and played with it while looking wistfully at the attractive toy. By contrast, the children punished late were much more likely to play with the attractive toy while watching the door anxiously in case an adult appeared.

Children, of course, are much more complex creatures than dogs, which is evident in the many other factors that interact with the timing of children's punishment to make it maximally effective. Social development researcher Ross Parke found that punishment is likely to be most effective if (1) it is delivered consistently, (2) it is delivered by a person whom the child likes and sees as warm and caring, and (3) it is accompanied by a reasoned explanation. These three guidelines may seem easy to implement in theory, but they can be surprisingly difficult to honor in reality. Most caregivers show at least some inconsistency in administering punishment or they sometimes fail to provide full explanations. For example, if a father is completely exhausted after a rough day at work and his 4-year-old daughter is making a fort in the yard with her bed linens, he may just sigh and let it happen rather than going to the trouble of scolding the child, explaining why the behavior is wrong, and then dealing with the resulting tears and sadness. He may know full well that it is important to be consistent and to explain precisely why the behavior is wrong and why punishment is occurring, but it is not always easy to follow through with that knowledge.

The greater effectiveness of warm and caring punishers may seem surprising, given the folklore about children behaving like angels around the cold, heartless schoolmaster. But Parke's findings suggest that such harsh taskmasters may only be effective in ensuring compliance when they are present. Such strictness may not prompt children to internalize the appropriate behavior so that they comply with it even when they are alone. This principle leads to an important point: punishment should be used sparingly. If it occurs too frequently, the child may no longer perceive the adult as warm and caring, which is what makes the adult so effective with the child.

Finally, in the real world, an adult cannot always be present when the child is just beginning an immoral action. But when punishment has to be administered long after a transgression, several cognitive techniques can be used to help the child bring to mind the misbehavior that occurred hours earlier. One intriguing technique involves "reliving" the act. For example, if a child put glue in a classmate's winter hat just before it was worn during recess, the parent cannot be there to impose punishment at the beginning of the action. But that evening, the parent can remind the child of what was happening at the time of the misbehavior, asking him to think through his earlier motivations and actions, and then administer the punishment. For example, a dialogue of the following sort might occur:

Parent: Johnny, do you remember when you snuck off to the coatroom today with that jar of glue from Ms. Stebbin's desk?

Child: Yes.

Parent: And do you remember how you thought it would be funny to put the glue in Susie's hat so that it would get all over her hair during recess?

Child: Yes.

Parent: Do you remember thinking how Susie would look and how everyone would laugh at her?

Child: Yes.

Parent: Well, it was very wrong to want to do that to Susie, and it was a terrible way to treat her. The glue was painful to get out and made her feel embarrassed. You should be ashamed of yourself [followed by more scolding and revocation of privileges].

In short, much is known about how to deliver effective punishments that can help children develop the internal ability to inhibit certain behaviors. The learning theorists' work on punishments may not lead to a better understanding of the nature of guilt and conscience, but it does provide an understanding of the cognitive repertoire that can be used in punishing the child, including both the explanations that should accompany punishments and the methods for helping the child "relive" an experience so as to make the punishment coincide with things the child thought and felt at the beginning of the misbehavior.

It is important to remember, however, that even when punishments are delivered in an ideal way, they can have negative side effects over time. Children may come to avoid the punishing adults, thus weakening emotional bonds with caregivers when they are most needed. Even worse, children may start to imitate the patterns of punishment themselves, using them aggressively and inappropriately on others. Certainly children who have experienced a great deal of excessive physical punishment are much more likely to be physically abusive as adults, both with their spouses and with their children. Indeed, one extensive **meta-analysis**—statistical analysis of the data from many studies—examined the relationship between physical punishment and several other variables (Gershoff, 2002). Despite repeated claims that physical punishment might have an important place in child rearing, the meta-analysis revealed no positive effect beyond an association with higher rates of immediate compliance. In all other respects, physical punishment was consistently related to negative outcomes, such as increased aggression against others and a weaker internalization of moral values. Table 12.5 shows these patterns of associations with physical punishment.

Q: What are some of the negative side effects of using physical punishment on children?

Not all studies paint a uniformly negative picture of physical punishment. For example, a light spanking,

TABLE 12.5 Associations between physical punishment and various measures in childhood and adulthood. Experiencing more physical punishment is associated with various kinds of effects during both childhood and adulthood. All of the associations are statistically significant, but they vary in degree. A small association means that physical punishment has a significant but modest correlation with a measure, whereas a large association means that the correlation is quite high. Adapted from Gershoff (2002).

Type of Effect	Size of Association
In childhood	
More immediate compliance	Large
Greater likelihood of suffering physical abuse	Medium to large
More antisocial behavior	Medium
Poorer mental health	Medium
More aggression	Small to medium
Less internalization of morals	Small
In adulthood	
More aggression	Medium
More antisocial behavior	Small to medium
Poorer mental health	Small
Greater likelihood of abusing one's child or spouse	Small

accompanied by both a reason and a genuine concern for the child's welfare, may not have worse effects than nonphysical forms of punishment (Benjet & Kazdin, 2003; Larzelere & Kuhn, 2005). In addition, the negative effects of physical punishment may vary across cultures and even among subgroups within a culture (MacKenzie et al., 2011). The negative associations with physical punishment summarized in Table 12.5 tend to hold for European-American families in the United States, but physical punishment does not always show such undesirable associations in African-American families. Indeed, careful, appropriate physical punishment is more associated with positive outcomes than with negative outcomes in certain cultures (Lansford et al., 2004; Larzelere, 2000).

Examining punishment across a wider range of cultures, including those of China, India, Italy, Kenya, the Philippines, and Thailand, reveals quite substantial variations in the amount of physical punishment parents use (Lansford et al., 2005). For example, parents in Thailand are much less likely to use physical punishment than parents in Kenya. Moreover, in cultures where physical punishment is common, it is not nearly as strongly related to childhood behavior problems as it is in cultures where physical punishment is less common (Lansford et al., 2005).

Even in relatively similar cultures, there are substantial variations in the acceptability of physical punishment. For example, its acceptability varies quite dramatically within the countries of the European Union, and in general it is considered less acceptable in countries whose governments have made prominent efforts to raise public awareness of the effects of physical abuse on children (Gracia & Herrero, 2008). Socioeconomic strain and the lack of social support structures can also cause very substantial variations in the prevalence of physical punishment within a culture (MacKenzie et al., 2011). For example, in the state of Kentucky, physical punishment in the school is more prevalent in counties that have higher incidences of families living in poverty and lower incidences of involvement in community groups such as churches (McClure & May, 2008). In addition, males, single parents, and those associated with some fundamentalist religions are more likely to use physical punishment (Xu et al., 2000). These patterns of variation make it clear that social policies designed to ameliorate the negative effects of physical punishment must be very sensitive to the social contexts in which it occurs.

Modeling Theory and Moral Behaviors We have so far largely focused on the punishment of antisocial behaviors. It is more difficult and rare to punish a child for not being especially altruistic. There is, however, another form of social influence on morality that seems to apply equally to both antisocial and prosocial behaviors. Known as **modeling theory** (or **social learning theory**), it relies on the likelihood that people tend to reproduce behaviors that they see others performing (Bandura, 1971).

Hundreds of studies have shown that both children and adults become more likely to perform a wide variety of antisocial behaviors after seeing someone else engaging in the behavior. In the most famous studies of this phenomenon, conducted by Albert Bandura and his associates, children observed an adult being physically aggressive toward an inflatable toy called a Bobo doll (Bandura et al., 1961). The adult modeled a series of aggressive acts toward the Bobo doll, including hitting, kicking, and sitting on it (see Figure 12.19). After the children patiently watched this rather strange adult behavior, they were left alone with the Bobo doll and were covertly observed by the experimenter to see what they would do. As Figure 12.19 shows, the children often copied the adult's violent behavior with frightening intensity and specificity.

Of course, the Bobo doll study presents children with a bizarre experimental setting in which they may have thought they were taking part in a game rather than really being aggressive. But an extensive series of follow-up studies by both Bandura and others suggests that in real-life situations, too, seeing others modeling aggressive and antisocial behaviors can increase the prevalence of similar behaviors in those who observe the aggressive behaviors (Bandura, 1971; Bandura & Walters, 1963). Moreover, because the behavior that is imitated is often highly specific, it is difficult to explain the modeling effect as simply a general loosening of inhibitions. Even without any reinforcement, children become more likely to steal, cheat, lie, hit, or tease after observing models doing so.

At one level, modeling theory seems to offer a full account of how both antisocial and prosocial behaviors emerge, suggesting that children will reproduce either type of behavior after seeing it modeled by others. Moreover, Bandura and his colleagues have shown numerous ways in which modeling can be made more effective. A child is more likely to copy the model's behavior if she likes and respects the model, if the actions are clear and salient, and if the model frequently performs actions that are easy to imitate. Anyone who masters the research on modeling can use that knowledge to change children's behavior. Yet, at the same time, modeling theory has little to say about why children copy models. Instead, it often focuses on the variables that make children more likely to imitate them. To explain why children copy some people's actions and not the actions of others, however, requires a broader theory of identification, respect, and affiliation with others. To explain why children find some actions more salient than others requires an account of how children perceive and encode social actions. The modeling approach has provided a framework, but there is still a need for more comprehensive theories in each of these areas.

In the realm of prosocial behavior, we have seen that young children often engage in actions that suggest an intent to benefit others rather than themselves. We have also seen that children and adults vary a great deal in the extent to which they act prosocially. Many researchers have turned to modeling theory to explain these individual differences, in part because it offers a clear explanation of how caregivers might encourage prosocial behavior. If you have a warm relationship with your child, and your child respects and identifies with you, then the stage is set for effective modeling. When the child sees you engage in a prosocial behavior that she can easily understand and reproduce, she will more likely reproduce the behavior. This pattern of influence has been supported both in studies in which adults and children who

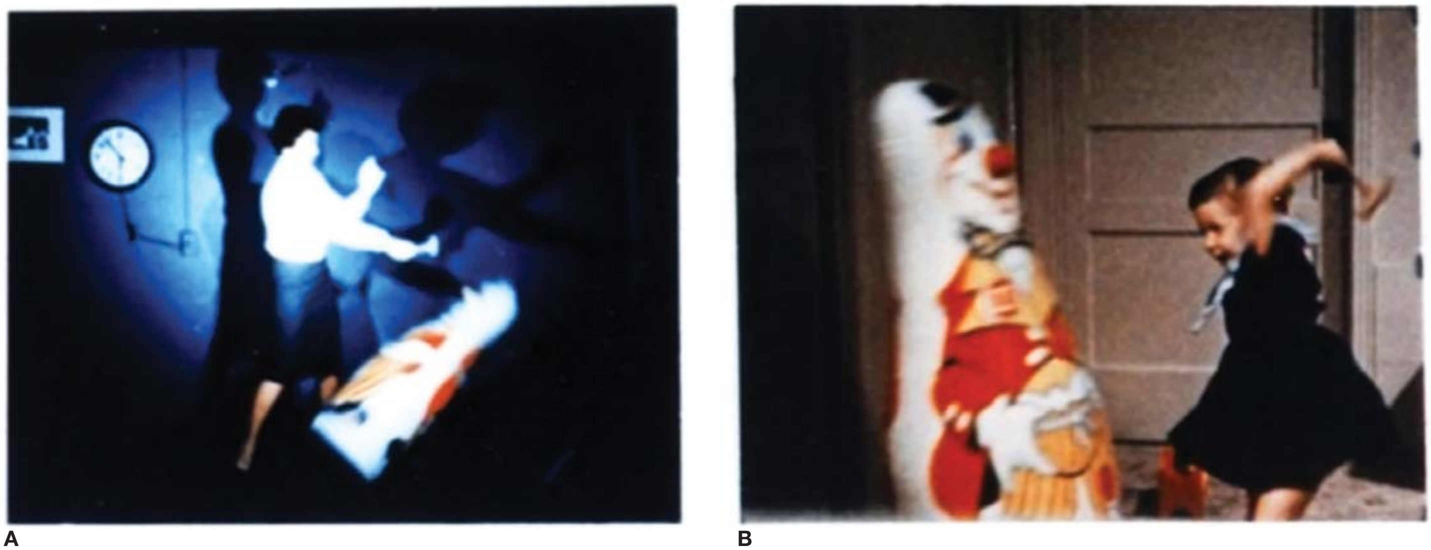

FIGURE 12.19 **Modeling aggressive behavior.** Children have repeatedly been shown to reproduce quite specific behaviors modeled by adults, whether it is the somewhat bizarre act of physically assaulting a Bobo doll or the verbal assault of younger, more helpless individuals. From Bandura (1971).

act altruistically are interviewed later and in experimental studies examining the effects of prosocial modeling on children (Eisenberg & Fabes, 1998; Hoffman, 1977).

Q: What form of socialization seems to be most natural for prosocial behavior?

Parent-Child Interactions and the Development of Conscience Although it might seem that more cognitive views of how parenting instills a sense of morality are quite recent, the earliest version of this approach was proposed by Sigmund Freud (1923/1960). Like much of Freud's work, this theory was based on Freud's idea that the mind is composed of three parts: the id, the ego, and superego. The **id** appears first in development and represents basic desires and drives. The **ego** appears next and enables the child to channel and direct the id. Finally, the **superego** appears last, when true morality is thought to emerge. According to Freud, younger children are unable to be truly moral because they are governed solely by the id, which responds only to impulses and lacks any moderation or controls that make it possible to delay gratification. Only later, in toddlerhood, does the ego start to emerge as the regulator of the id's instinctual passions. But the ego merely keeps these passions in check until they can be satisfied. It has no sense of right or wrong. Only the superego, which is not fully formed until around age 6, is capable of providing an internal moral sense. Freud believed that before the superego develops, only external controls, such as punishments and reinforcements from parents, can guide a child toward moral behavior.

Freud's theory of moral development is marred by many problems. It emphasizes the growth of the superego out of Oedipal and Electra conflicts, in which children subconsciously resent their same-sex parent out of jealousy for the other parent's affection. Freud's ideas about these conflicts led him to make a variety of predictions, including the erroneous claim that women are less "moral" than men because the resolution of the Oedipal conflict by boys more strongly promotes the development of the superego than does the resolution of the Electra conflict by girls. Moreover, Freud's claim that guilt and conscience do not develop until age 6 is suspect, given reports that children as young as 2 or 3 clearly show guilt and remorse (Hoffman, 1982). And his more detailed predictions about the effects of various parental styles and dispositions on children's emerging superegos also fail to hold true (Hoffman, 1970). Let us therefore consider more contemporary approaches to how parents and other caregivers might socialize children to have a moral sense.

Parents do not merely "instill" their values in the child. Rather, the child also plays a role in his or her own moral development. Just as older views of cognitive and perceptual development saw the child as an empty vessel or a blank slate that passively receives knowledge, so do many views of moral socialization see the parents and society as providing the child with the right sorts of values. Yet, there is every reason to think that such a passive model of the child works no better for morality than it does for cognitive and perceptual development in general. Indeed, it is important for caregivers and developmental researchers alike to be sensitive to the ways in which children actively construct their own moral sense and behaviors, and not always by simply imitating those of adults (Grusec & Goodnow, 1994). As parents, especially, we must recognize that our children will not always reason morally as we do, nor will they always come to precisely the same conclusions that we do. But we can hope that they will become moral individuals in a rich, deep, and self-constructed sense. Moreover, different children take very different pathways to achieving a conscience, and the same style of parenting that is effective with one child may be ineffective with another (Kochanska, 1997).

The development of conscience is often linked to the emergence of feelings of shame and guilt (see Figure 12.20). These feelings often motivate people to act on their conscience. Young children show intriguing individual differences in their tendencies to react to problems with either shame or guilt. In one study, children between 2 and 3 years old were allowed to play with toys belonging to the experimenter, and during the play session, they were led to believe that they had broken a toy (Barrett et al., 1993). The children were classified according to their reactions to the broken toy. The "avoiders," who seemed motivated by shame, avoided the experimenter when she returned to the room. They also did not tell the experimenter of the mishap and were very slow to try to fix the situation. The "amenders," who seemed motivated by guilt, did not avoid the experimenter and were quick to tell her that the toy was broken and to try to repair it themselves. Clearly, children with these different styles might respond very differently in similar real-life situations.

Shame orientations generally seem to have more adverse psychological correlates, such as higher rates of depression, in older children and adults (Kim et al., 2011; Tangney et al., 2007). Shame is considered more painful because it negatively impacts the self more directly, creating feelings of being helpless and worthless as well as exposing a person's flaws. In contrast, guilt is thought to focus a person's thoughts and feelings on a specific behavior rather than on the core sense of self and is generally less painful and devastating to a person. The early emergence of individual differences in the tendency to experience shame versus guilt raises important questions about the extent to which parents might be able to gently guide the child more toward a guilt orientation, and indeed, there are suggestions that different

A

B

FIGURE 12.20 Guilt versus shame. (A) Children who are motivated by guilt often focus on a particular behavior rather than on core feelings about themselves, whereas **(B)** children who feel shame often feel helpless and worthless.

parental interaction styles might lead to different self-conscious moral emotions (Lagattuta & Thompson, 2007).

Parents can also influence how sensitive their children are to different aspects of moral behaviors and their consequences. One study examined these effects by asking mothers of 4-year-olds to talk about their child's good and bad actions in the prior week. The researchers then analyzed the mother's comments to determine how often she referred to the child's feelings and intentions, rules, or the consequences of the child's actions. The extent to which the mother made comments focusing on such themes predicted the child's conscience development, which was measured in terms of compliance and internalization of certain values (Laible & Thompson, 2000). In other words, the way a mother talks about her child's actions, both to the child and to others, may affect the way the child thinks about moral issues and acts on them (Grusec et al., 2000). More generally, parents who adopt a noncoercive, highly interactive, and sensitive parenting style that is infused with positive emotions and that uses very gentle discipline strategies tend to foster an earlier development of conscience in their children (Kochanska & Aksan, 2006).

Developmental psychologists have learned a great deal about how patterns of child rearing and socialization can affect a child's moral development (Bugental & Goodnow, 1998; Eisenberg, 2000; Kochanska & Aksan, 2006; Shweder et al., 1997). Much of that research is also closely connected to the broader issues of socialization discussed in Chapters 14 and 15, concerning how the child becomes part of a family and society. Throughout these discussions, one important caution to keep in mind is that correlations between parenting styles and children's behaviors are just that, correlations. Explaining these patterns requires a careful investigation of whether shared genetic factors, similar environments, and the children's effects on their parents may also contribute to the correlation—instead of, or in addition to, parents' effects on their children. We will return to these issues in more detail in Chapters 13 through 16.

Conclusions

Morality is a complex, multifaceted aspect of being human. We reason in moral ways that are distinct from reasoning about such things as social conventions and physical laws, and these distinctive ways of reasoning seem to appear quite early in development. Within the realm of morality itself, there are further differences. When we are quite young, we can empathize with others in need, and yet that empathy relates only indirectly to altruistic reasoning and to prosocial actions. Similarly, aggressive feelings are related to antisocial reasoning and behaviors, but they are not the same thing. We can have hostile and aggressive feelings but not necessarily act on them. Moreover, the reasoning associated with such feelings may change over development with the emergence of more sophisticated ways of understanding situations and other agents. We can reason about many moral domains, including sharing resources, fairness and justice, and care, in ways that show their own developmental trajectories and that can be relatively compartmentalized (Killen, 2007). Finally, all kinds of moral reasoning are linked in subtle and complex ways to behavior, although there is no easy, straightforward way of translating moral beliefs into actions.

Despite this pluralism and the rapid state of change in research on moral development, some general themes in this area do emerge and reflect themes we have discussed in earlier chapters. First, the idea that the child as an active constructor of morality rather than a passive recipient is intrinsic to Kohlberg's approach and to many other theories of moral reasoning, such as Gilligan's, Damon's, and Eisenberg's. It is less intrinsic to many older theories of socialization and to current political arguments about instilling moral values in children. But most current, sophisticated views of socialization do seem to recognize that the child is an active participant in the socialization process.

A second familiar theme is that patterns of moral reasoning and behavior show less dramatic developmental shifts than were formerly assumed to be the case, and many aspects of moral development are significantly influenced by situational factors. Of course, in some situations, older children tend to use more complex patterns of moral reasoning than do young children, but even younger children can grasp these patterns when they are carefully simplified and made relevant to them.

On a related note, cross-cultural research suggests that there may not be universals of moral reasoning in the sense of everyone everywhere evaluating certain kinds of moral dilemmas in the same way. At the same time, however, cultures do not differ so dramatically that we cannot find common ground with other groups. There may be a universal collection of moral reasoning systems, and cultures may emphasize (or downplay) different moral components, depending on which situations and social structures are most pervasive in those cultures.

Finally, as we look back to the two views of morality introduced at the beginning of this chapter, it is now clear that young children are not amoral in the manner we assume holds for most animals. Within their first 2 years, children show compassion, selfishness, and a range of other behaviors indicating an early moral sense. It is also clear that young children are neither primarily moral nor immoral. At all ages, children show both prosocial and antisocial behaviors. Children share with adults a tension between good and bad impulses.

STUDY AND REVIEW

SUMMARY

The Development of Moral Thought

- One classical view of how children come to be moral beings sees the young child as having an inherently moral nature, sometimes of good, sometimes of evil. A different view sees the young child as essentially amoral and too immature to be considered capable of either moral judgment or culpability for actions.
- Evolutionary psychology and cultural psychology have each offered more recent views of the origins of moral thought. The evolutionary perspective emphasizes moral universals that are part of humans' biological heritage, and cultural psychology focuses on the influence of culture on moral values.
- Although moral thought and moral action are intimately related, it is clear that they are not the same thing and that one does not always predict the other. For that reason, it has been most natural as a research strategy to focus on either moral judgment in its own right or on factors that influence the emergence of moral and immoral behaviors.
- Piaget formulated his theory of the development of moral thought based on observations of how children come to understand game rules. He proposed a series of three stages of moral reasoning (premoral, heteronomous, and autonomous stages) based on the child's developing concepts of rules, of culpability, and of appropriate justice.
- As with much of cognitive development, a closer look at the evidence for stage theories has revealed serious problems. Rather than an early inability to engage in certain kinds of moral thought, developmental differences in moral reasoning seem more related to a wide variety of variables not directly linked to morality, such as social conventions and an inability to remember an entire sequence of events. In addition, Piaget's attempts to draw inferences about moral judgment from studying children's conceptions of game rules are problematic because children's understanding of social conventions develops quite differently from their understanding of morality.
- Lawrence Kohlberg's work largely superseded Piaget's theory. Kohlberg advocated a theory of moral development with six numbered stages divided into three levels (preconventional, conventional, and postconventional). He used moral dilemmas to uncover forms of moral reasoning that he believed revealed children's beliefs about what morality really is. As later researchers more extensively probed Kohlberg's stages,

however, it became clear that they do not represent an invariant sequence across cultures and genders.

- Carol Gilligan proposed three stages of moral development (preconventional, conventional, and postconventional) that emphasize care, concern, and empathy. According to Gilligan, females progress through the stages more quickly than males. Later research did not consistently find a gender difference, however, in moral reasoning.
- Findings showing that the same individual can use several distinct forms of moral reasoning, depending on the situation, gave rise to a pluralistic view of moral thought. In this view, children and adults have several systems of moral interpretation available to them. Different kinds of interpretations predominate among different people and groups, but all interpretations are potentially available to most groups, given the right context. Moral development looks less like a progression through stages of moral reasoning and more like shifts in terms of what forms of reasoning are used in specific situations. Younger children have trouble understanding some complex moral situations, but these difficulties may be largely due to the complexity of the description rather than differences in moral reasoning ability.

The Development of Moral Behavior

- A different research tradition has focused more on the development of moral behavior itself. Adults and children may not be morally consistent across situations. A moral offender in one situation may be a moral upholder in another. It is not at all easy to reliably predict moral behaviors from moral reasoning patterns. People of any age may know what is right, but still fail to do it.
- Antisocial behavior does not show obvious developmental trends, and there is no evidence that people cheat, steal, or lie less as they age. Nonetheless, the particular forms of the antisocial behaviors may change with age as the person becomes more sophisticated. Prosocial behavior does seem to become more common with age, although even very young children can show some forms of altruism, such as instrumental helping. There are, however, powerful individual differences among children (and adults) in the incidence of moral behavior. Scholars have attempted to explain these differences both in terms of underlying differences in temperament and personality and in terms of social influences.
- Temperamental and personality differences in moral behavior have focused not on morality itself but on psychological components that can influence immoral behavior. Problems with impulse control, difficulties delaying gratification, deficits in the ability to feel empathy, and low levels of arousal have all been associated with the development of antisocial behaviors. Some behavior problems have significant heritabilities, so there is some reason to believe that psychological components may have some biological basis related to genetic variation. Children who show very early behavioral problems in preschool are also statistically more likely to have more serious behavioral problems later in life, which some have argued supports the notion that these behaviors have a genetic basis.
- Correlations between early behavioral problems and later ones may also be caused by a constant adverse environment or manner of parenting. Albert Bandura's research into modeling theory showed that children will reproduce quite closely the actions of models like parents and other older individuals around them, including antisocial and immoral behaviors.
- Some forms of punishment can cause long-term changes in behavior, but the timing of the punishment is extremely important, as is making sure the child understands the rationale for the punishment. Other forms of punishment can be ineffective or cause negative side effects in many situations, as in the case of physical punishment.
- Children may develop moral consciences that are either driven largely by guilt or shame. Children who feel guilt are more likely to try to repair a wrong in the presence of an adult than those who feel shame.
- It still remains to be seen whether differences in parenting styles cause differences in children's morality or whether, for example, the similar genotypes and/or environments that parents and children share are the true causes of any links between parents' and children's behaviors.

THOUGHT QUESTIONS

1. Adults will often rationalize a moral transgression after the fact in an attempt to justify it or reduce its perceived severity. Discuss how the ability to engage in such rationalizations might develop in childhood. Would it be possible for some form of rationalization to be present even in preschoolers? How might early emerging rationalizations differ from later ones?
2. Under what circumstances, if any, do you think it is acceptable to use physical punishment with a 7-year-old child? How do you justify that choice in terms of the research literature?
3. Under what circumstances might rapid emotionally driven moral judgments result in more ethical decisions than slow, deliberative, and more cognitively based ones? Are there useful rules of thumb that emerge from your analysis? Are there developmental implications?
4. Some politicians have suggested that having children read stories about historical figures who show great moral character will lead to more moral children. Consider the feasibility of such an approach and how it might have unanticipated consequences.

Conclusions

Summary

When you come across your baby pictures or watch a video from your childhood, what kind of connection do you feel to the person in the pictures? If you have no memory of these particular early experiences, the images can evoke a sense of great distance from your younger self, along with some feeling of being less connected to that self. But when you see a recent photo of yourself or encounter your reflection, you almost always recognize and identify with this self-image automatically.

Many years ago, as we were looking through an old album, our 3-year-old became fascinated with a series of pictures showing him riding a pony in Yosemite National Park. Before we had even mentioned the pictures, he pointed to them and excitedly said, "That's me! That's me!" Somehow, either from contextual cues or from the resemblance between the child in the photograph and himself, he recognized that the photo showed him and not another child. This seemingly simple act requires not just having a sense of self, but also being able to use certain cues to recognize our own image. These abilities are just the beginning of a much richer awareness of the self, along with the ability to think about our own mind and the minds of others and an understanding of how people's beliefs and traits are linked to behaviors.

A great deal of complex development occurs as children come to understand themselves as well as the minds and emotions of others. In this chapter, we will consider how children gain this social understanding of themselves and others and how this understanding relates to motivation and actions. Chapter 14 considers how children, as socially aware individuals, become parts of families. Chapter 15 broadens the discussion further to explain how children take part in ever larger social communities, from their peer group to their whole culture.

We will begin this chapter by focusing on how children develop concepts and representations of themselves. We will see that there is no single sense of the self. Rather, there are several different senses that emerge at different times to eventually create a more integrated mature sense of self in middle childhood. Then we will turn to the classic "mirror test," in which the child recognizes that he is the person in the mirror, and we will ask how this ability to recognize himself in a mirror relates to the various senses of self and their developmental courses. From there we will consider how children value and regulate themselves and their behaviors. Next we will see that the relation between self-esteem and various developmental outcomes is more complex than some popular accounts might suggest. We then consider the relation between self-esteem and self-efficacy—namely, the sense of having an influence on the world. While revisiting the topic of self-regulation, we will address broader questions regarding senses of self and self-awareness.

We build on these ideas to discuss how children develop an understanding of the minds of others and how they come to have insight and control with respect to their own mental and emotional states. People in all cultures think not only about their own minds but also about other people's minds. This ability to think about other people's beliefs and desires and how those beliefs and desires predict and explain behavior is referred to as **theory of mind**. It is critical to mature social interactions. We have seen in Chapters 5 and 6 that even infants are aware of social entities as being distinct from nonsocial ones, and by 18 months of age, these children are clearly able to make inferences about a person's behavior in terms of his or her goals. But these social skills, impressive as they might be, are only a small part of what comes to be a full-fledged theory of mind. Lastly, we will consider how this understanding of the mind unfolds in childhood, becoming ever more important in social interactions, and how individuals make attributions about themselves and others. The first place to start, however, concerns thoughts about the self.

Self-Concepts and Self-Representations

The developmental psychology of the self has several components, including the different ways of thinking about and being aware of who we are. It also involves an understanding of the ways in which external devices, such as mirrors, videos, or photographs, can represent us. Finally, it involves the linkage of larger sociocultural roles, such as being a boy or a girl, with knowledge of our own sex.

Senses of Self

One way to understand the development of the child's ability to think about minds and behavior is to look first at how the child develops a **sense of self**—the various ways an individual thinks about himself and has distinct kinds of self-awareness. It is tempting to think that the development of a sense of self is a single psychological event—something like consciously thinking, "I am different from others in a special way." Looking more closely, however, it is apparent that people sense the self in several ways that have their own developmental pathways, rather than forming one monolithic sense of self.

Neisser's Five Senses of Self The idea that people have several senses of self has been around for some time. In 1890, the great American psychologist and philosopher William James described four senses of self: the physical self, the mental self, the spiritual self, and the ego (Gallagher, 2000; James, 1890/1950). One of the many researchers who have elaborated on this view is the psychologist Ulric Neisser. His perspective touches on many of the developmental studies we have examined in earlier chapters. Neisser argued for five senses of self: *ecological*, *interpersonal*, *extended*, *private*, and *conceptual* (Neisser, 1988; Neisser & Fivush, 1994).

These different senses of self emerge at different points in development, but it is important to realize that the sense of self continues to develop over the years. Thus, earlier senses of self are not simply serving as building blocks for later ones, as we have seen in many stage theories. Rather, all the different senses of self coexist in adults. We will consider each of Neisser's five senses of self in a bit more detail.

The **ecological self** is our sense of where we are as we move through the world (see Figure 13.1). Humans and many other species have this perceptual and motor sense of self. The ecological self utilizes what our senses perceive, calculating and responding to where we are relative to objects in the external world. It is automatic, immediate, and nonverbal. To use a term coined by the psychologist James J. Gibson, it is also "directly perceived," meaning that the newborn has an ecological sense of self instantly, from the first moment that she perceives the world. This sense of self is evident when, for example, an infant flinches at the approach of a looming object, clearly showing a sense of the self being threatened as the object approaches on a collision course (Ball & Tronick, 1971; Schmuckler & Li, 1998; see Chapter 3). The ecological self becomes more sophisticated as the child's motor and perceptual skills develop.

The **interpersonal self** is the sense of interacting with other intentional agents. It arises automatically and without reflection. This inherently social sense of self includes a sensitivity to the reciprocal nature and the timing parameters of social interactions. It is roughly the immediate sense of "I" and "you" that arises when we first encounter and interact with another. Humans share this sense of self with many other social species and it does not, in its early forms, require the ability to think about how another person's beliefs and desires explain that person's actions. It, too, may have its earliest origins shortly after birth (see Figure 13.2). We saw evidence for an early emergence of the interpersonal self in Chapter 6. Infants under 2 months of age become distressed when their mothers do not interact in a manner that fits the natural timing of back-and-forth social interactions (Adamson & Frick, 2003; Bertin & Striano, 2006; Cohn & Tronick, 1988, 1989; Field, 1977; Gunning et al., 2013; Nadel et al., 1999; Tronick, 1989; Murray & Trevarthen, 1985).

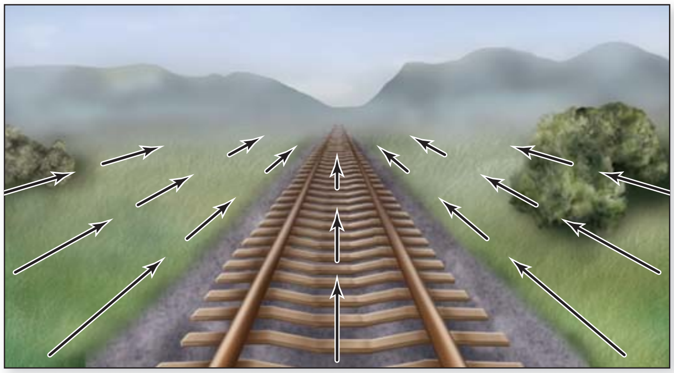

FIGURE 13.1 The ecological self. When a child is moving through her environment, such as traveling down a train track as the world flows by, she experiences a sense of self-presence and movement in the environment.

FIGURE 13.2 The interpersonal self. When interacting with other social agents, even infants appear to have a sense of the interpersonal self.

The **extended self** is our sense of ourselves as progressing along an autobiographical timeline. We think of ourselves as linked to the past (through memories) and to the future (through beliefs about what will likely happen next). As we saw in Chapter 10, the development of this sense of self in the preschool years may be an important factor in explaining the point at which infantile amnesia ends (Fivush & Schwarzmueller, 1998; Nelson & Fivush, 2004).

The **private self** is our sense that we have certain privileged experiences that no one else has access to unless we choose to communicate those experiences to others. The private self includes our dreams, the unique perspectives and background knowledge that we bring to any situation, and our unique knowledge of how it feels to move our body in a certain way (see Figure 13.3). These different aspects of the private self may not all develop at the same time, but they typically emerge in the later preschool years. The emerging private self may be seen when preschool children start to appreciate that their own point of view may differ from those of others. We have seen evidence of the development of this sense of self in circumstances where children do not show

FIGURE 13.3 The private self. At some point during the late preschool years, children start to understand that dreams are part of the private self.

egocentrism, including the development of narrative skills (see Chapter 8) and their understanding of spatial relations (see Chapter 9). We will see later in this chapter that children's developing understanding of mental lives can include a sense that different people will have different mental states and privileged experiences.

The **conceptual self** includes our sense of the roles that we occupy in broader social and cultural contexts. It can include notions of gender roles, family roles (as a child or parent or sibling), tribal or ethnic or national roles, or roles as a person in contrast to other living creatures. This may be the most sophisticated sense of self and the one most influenced by other people and the surrounding culture. In short, the conceptual self includes the various ways in which high-level cognition helps articulate who we are relative to others. In Chapter 14 and especially Chapter 15, we will see several ways in which children begin learning these roles in the preschool years and continue through elementary school, adolescence, and young adulthood.

Neisser's five senses of self, summarized in Table 13.1, represent some of the different facets of the self that have been uncovered by the large and diverse body of research on perceptual and cognitive development. The same developmental phenomena potentially could be more finely divided into six senses or collapsed into four, and whether these particular senses of self are precisely the right ones will continue to spur investigations for many years to come. (For alternative models, see Damon & Hart, 1988; Harter, 1998.) The key point is that the sense of self is not based on a single insight that children have at some point in development, nor is it acquired by gradually developing one kind of understanding. Rather, there are qualitatively different senses of self. Each one follows its own developmental journey, even as it interacts with other senses of self and contributes to an even higher-order self-concept.

Sense of Self	Time of Emergence	Characteristics
Ecological self	Birth onward	Sense of where we are as we move through the world Perceptual and motor awareness Automatic, immediate, nonverbal
Interpersonal self	Shortly after birth onward	Interacting with other intentional agents Automatic, without reflection Inherently social
Extended self	Age 4 onward	Autobiographical timeline Understanding that we are linked to the past and having the ability to think about the future
Private self	Age 4 onward	Understanding that we have privileged experiences no one else has Knowledge, dreams, perspectives
Conceptual self	Age 4–5 onward, with major growth in middle childhood and beyond	Most influenced by others and by ambient culture Social roles (gender roles, family roles) Able to articulate who we are relative to others

TABLE 13.1 Neisser's five senses of the self. Neisser (1988) argued that there are five distinct senses of the self rather than a single unitary concept.

Q: Describe five different senses of self, how they develop, and their implications for cognitive and social development.

The Mirror Test and Self-Concept

One of the most studied aspects of the sense of self concerns our ability to recognize ourselves in a mirror. Experimenters have tested this self-recognition ability in young children and various animals using a technique called the **mirror test**. This method involves putting an artificial mark on the subject and testing whether, when faced with a mirror, the subject realizes that the mark seen in the mirror is actually on the self and not on another individual (Gallup, 1970). When this test was first used with chimpanzees, a bright red mark was placed on a chimp's forehead when it was under anesthesia. The chimp was put in front of a mirror, and when it awoke, researchers observed whether the animal's behavior suggested awareness that the mark it saw in the mirror was on its own head.

Data from the mirror test have been vigorously debated, but those debates tend to converge on some common conclusions (Anderson, 1984; Heyes, 1998). Even though many animals can be taught to use mirrors to find hidden objects, only humans, some of the great apes (chimpanzees, bonobos, orangutans, and possibly gorillas; see Figure 13.4A), elephants, and bottle-nosed dolphins have passed the mirror test (Boyson & Himes, 1999; Plotnik et al., 2010). In one study, bottle-nosed dolphins that had already become accustomed to mirrors on one side of their tank clearly passed the mirror test (see Figure 13.4B). The researchers used a waterproof marker to make a visible mark on the heads of some of the dolphins, and as a control, they used invisible ink to make the same mark on the other dolphins. Those with the visible marks spent much more time in front of the mirrors examining themselves than the dolphins whose marks were invisible. They also seemed intent on turning and positioning themselves in front of the mirror to get the best views (Reiss, 2011; Reiss & Marino, 2001).

Most children first pass the mirror test at around 18 months (see Figure 13.4C), but some children do not pass it until age 2 (Anderson, 1984; Lewis & Brooks-Gunn, 1979; Lewis et al., 1985). Before that time, they do not touch the mark on their own foreheads when they see it in a mirror, although they might touch the odd-looking mark on the "other child" in the mirror. Given that so few species pass the mirror test and that most of those species are either closely related to humans or otherwise thought to have high-level cognitive capacities, it is perhaps not surprising that creatures who pass the test have been credited with a sophisticated **self-concept**—namely, a conscious sense of the self as an independent agent in the world. In addition, some researchers have argued that the psychological processes that enable creatures to pass the mirror test are the same processes that enable a creature to have empathy for others (Gallup, 1998).

Q: What is the mirror test, and how is it related to the developing sense of self?

Variations on the Mirror Test It is difficult to say whether passing the mirror test reflects a full self-concept. Instead, it may tap into a child's more specialized ability to notice that a visual image moves in perfect synchrony with his own body and that the synchronized image corresponds to himself. With this kind of sensitivity, which has been called a **kinesthetic self-concept**, the child senses

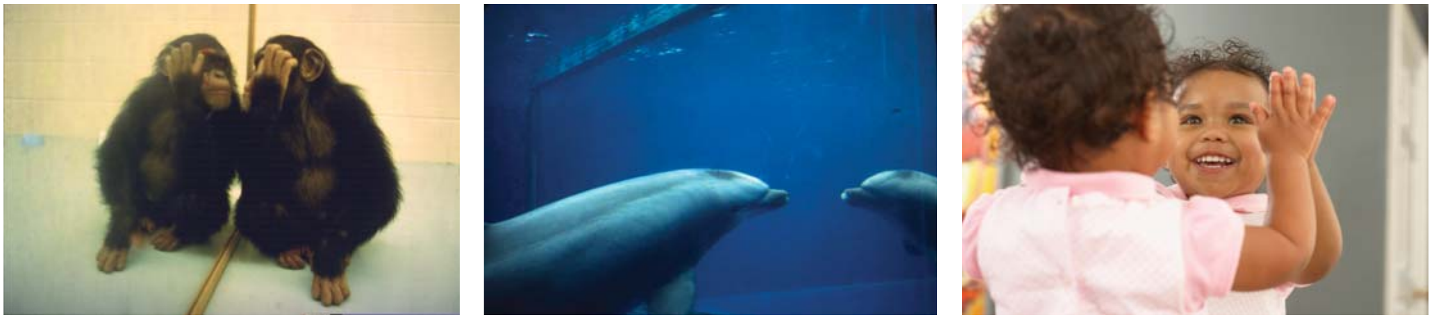

FIGURE 13.4 The mirror test. In the mirror test, a visible mark is put on a participant's face and is only visible in a mirror. When the participant sees the mark in the mirror, the critical question is whether he will touch the mark on the mirror or the mark on his own body. The relative rarity of this behavior across species has led some to argue that it is evidence for a true concept of self as well as the ability to put oneself in others' shoes empathically (Gallup, 1998). But it may be that the ability to pass the mirror test is only one part of the full self-concept. Pictured here are mirror tests with **(A)** a chimpanzee, **(B)** a bottle-nosed dolphin, and **(C)** an 18-month-old human infant.

a link between himself and the synchronous display without a deeper understanding that the display *shows an image of himself* (Mitchell, 2002). The kinesthetic self-concept resembles Neisser's ecological self, concerned with perceptual and motor awareness (Neisser, 1993).

Studies that substituted a video display for the mirror have supported this more conservative speculation on what it means to pass the mirror test. The video display was either synchronous with what the child was doing or there was a delay—sometimes as brief as 2 seconds—between what the child was doing and what she saw in the video. When the display was synchronous, the children would sometimes notice the dot in the video and then touch their own foreheads. But when the video was even slightly delayed, they did not touch their foreheads (Povinelli & Simon, 1998). They noticed the "other" child and sometimes called it by their own name, but they did not seem to recognize it as their own image. Not until they were almost 4 years old did children respond to the dot in the delayed displays by examining the same spot on their own bodies.

Based on these results, some have argued that the extended sense of self must emerge toward the end of the third year, allowing children to pass the delayed mirror test, and that passing the test in the synchronous condition shows only the earlier, kinesthetic sense of self. Interestingly, no other animals are known to pass the delayed mirror test (Povinelli, 1998). Children who are 2 and 3 years old also fail the test much more often with the simultaneous video than with mirrors (Suddendorf et al., 2007). This "video deficit" remains even when the video image is life-size and reversed, just as it would be in a mirror. For those reasons, the video studies cannot offer conclusive evidence that toddlers who pass the mirror test are relying on synchronicity alone.

Quite a few young children and many monkeys do seem to have some sense that mirror images of themselves are special, even though they may not know that the image is actually of themselves. Thus, infants as young as 4 months old behave differently in front of mirror images of themselves than in front of images of others mimicking them (Rochat & Striano, 2002). Similarly, capuchin monkeys behave differently in front of mirror reflections than in front of images of other monkeys (de Waal et al., 2005). Although neither the young infants nor the monkeys could pass the mirror test with the mark, they do have some rudimentary sense that self-images are different.

Researchers have also found that passing the mirror test does not simply require the child to be able to recognize an anomaly on his face, a plausible possibility given the special salience of faces. In a variation on the mirror test, researchers covertly put a sticker on a toddler's leg where the child could not directly see it. When the child was then put into a high chair in front of a mirror so he could see his legs reflected, he would reach for the sticker on his own body. The toddlers touched the leg stickers at the same age that they touched stickers on their faces.

This line of research also showed that toddlers rapidly update their self-representations. When a new pair of pants was attached to the high chair, such that the child could be slipped into them unknowingly, the child would not reach for the sticker when seeing his legs in the mirror (Nielsen et al., 2006). In contrast, if the toddlers could see the new pants as they were put into the high chair, they would touch the sticker on their leg after seeing it in the mirror. Apparently, when they did not realize they had on new pants, they thought that the legs might belong to another child; but with a brief cue that new pants were on their own legs, they passed the mirror test. Thus, when toddlers can pass the mirror test, they can do so for all parts of their bodies, and they readily update their sense of what those parts look like.

These results of the various versions of the mirror test reinforce the idea that the self-concept has many facets, each with its own developmental journey. The facets may interrelate and even form critical foundations for later-emerging ones. Thus, the kinesthetic or ecological sense of self may be a necessary step for the child to develop the extended self, even as all the facets persist and continue to develop.

Q: What are the limitations of the mirror test for providing a full account of the development of the self-concept?

Gender Identity

One facet of the self that seems quite closely anchored to the self-concept is **gender identity**, which means having a clear sense of being either male or female. Children seem to first learn their own gender category, as well as some of the surface trappings of gender (clothing, hair, and so on) at around 2 years of age. At about the same time, they also start to learn about gender-typical activities (for example, shaving versus putting on makeup) and gender-typical toys (for example, vehicles versus dolls; Halim & Ruble, 2010; Poulin-Dubois et al., 2002; Serbin et al., 2001). Finally, a sense of a deeper essential nature of gender—that there is something intrinsic and inside the body determining gender—starts to emerge at around 4 years of age (Gelman et al., 1986; Gelman & Taylor, 2000; Kohlberg, 1966). Interestingly, 5- and 6-year-olds view gender-related properties as just as intrinsic as animal species properties. In contrast, between age 10 and adulthood, individuals start to differentiate the two kinds of properties, seeing gender identity as more influenced by the environment and socialization (Taylor et al., 2009).

It seems obvious that at some point, children's ideas about gender are heavily influenced by noticing anatomical differences between their own sex and the other sex and then, over time, adopting the culture's views about how each gender should act. Thus, gender identity (perceptions of the self as a girl or a boy) and **gender roles** (how I should behave as a girl or a boy) have often been assumed to develop as one integrated complex. But this assumption is problematic, because some individuals who have a clear sense of their gender might still, for a variety of reasons, adopt nonstandard gender roles (for example, men who identify as males but dress as women). Despite these exceptions, however, it was assumed until the last decade or so that children learned both gender identity and gender roles by observing others in their culture (Lytton & Romney, 1991).

For that reason, for much of the twentieth century, if a genetically male infant was born with ambiguous or missing genitalia, doctors and psychologists often advised parents to raise the child as a girl (Money, 1975). Based on the idea that an individual's gender identity and sense of gender roles developed simultaneously, researchers believed that the child would assume that "her" anatomy was that of a girl and would therefore develop the gender identity of a girl. In many cases, if the genitalia were atypical or missing, additional surgery would be performed to make the infant appear more like a girl, the assumption being that this would make it even easier for the child to adopt a female gender identity.

One dramatic case involved identical twin boys, one of whom, as an infant, had his penis accidentally severed in a mishandled circumcision in 1966. John Money, a psychologist and expert on gender identity and sexual reassignment at Johns Hopkins University, was presented with the case and argued that the boy with the missing penis should be raised as a girl. This was reportedly the first time that sex-reassignment surgery was done on a boy who had neither genetic nor hormonal abnormalities. This case was widely discussed for years as an example of how either male or female gender identity could be imposed on genetically identical individuals based on how they were raised. Because the two boys were identical twins, they not only shared the same genomes, but also had experienced the same intrauterine environment. The prevailing view at the time was that a person's gender identity merely reflects how the person is labeled and how he or she is raised. Researchers believed that if you give a genetic male a female name and raise the child as a girl in all respects, the child will adopt the gender identity of a girl (see Figure 13.5).

Over the years, however, the assumption that gender identity is entirely learned and completely malleable has been severely challenged—and strong evidence against the original view came from this twin's case. That individual, who was raised as Brenda and never informed of "her" genetic maleness, nonetheless resisted being raised as a girl (see Figure 13.6). Despite extreme efforts to socialize Brenda as a girl, she rebelled against this socialization and was desperately unhappy (Colapinto, 2000). When she was informed at age 14 that she was born a genetic male, she chose to reverse all feminizing medical procedures and hormonal treatments and started living as a male called David. David later married a woman and became the father of several adopted children. Tragically, at the age of 38, David killed himself.

The extent to which gender identity is biologically determined has been studied more systematically in a large

FIGURE 13.5 Gender identity. Gender identity was thought to be completely a result of socialization practices, such as dressing girls and boys in distinctive colors, which might encourage children to feel similar to others of their own sex and different from those of the opposite sex from a young age. But there are some indications that children have a biologically determined sense of their sex that may overcome socialization practices.

FIGURE 13.6 Biological sex and gender identity. Although biologically male, Bruce Reimer was raised as a girl (and renamed Brenda) after a botched circumcision. Despite major attempts to socialize Brenda as a girl, which also involved feminizing hormones, the child never felt comfortable with that gender identity. As an adult, she changed her name to David, had male reconstruction surgery, and lived as a male, as shown here.

number of genetic males who, like Brenda, were raised as females—in these cases, because of atypical genitalia at birth (Reiner, 1997, 2005; Yang et al., 2010). Quite remarkably, a large majority of these genetic males, even after being raised as girls for many years and not knowing their genetic sex, stated that they felt themselves to be male. Other studies also support the idea that biological gender, as specified by X and Y chromosomes and the hormonal environments they typically induce, has an important influence on gender identity (Bao & Swaab, 2011; Savic et al., 2010). Nonetheless, as we will see in Chapters 14 and 15, socialization can have a strong influence as well (Cohen-Kettenis, 2005; Meyer-Bahlburg, 2005).

The fascinating question that arises is how the genetic and hormonal differences between males and females can cause such cognitive differences. What physiological differences can lead a child who is told that "she" is a girl and is made to look like a girl and act like a girl still feel comfortable only as a boy? Two possibilities arise. One is simply that the child prefers certain activities that are associated with boys, despite his parents' attempts to instill other preferences. Perhaps the child is more aggressive and prefers more rough-and-tumble activities. Perhaps the child prefers focusing on physical objects, such as blocks and vehicles, rather than on social interactions and conversations. The child might then notice that boys prefer the same activities and come to identify with them. We could call this the similarity explanation. An alternative explanation is that aspects of the concept of being male or female are genetically and hormonally predetermined. This second view may seem implausible, but the first explanation has problems as well, since we all know of young girls or boys who prefer activities associated with the opposite gender and yet identify strongly with their own gender. In addition, the first explanation depends on actively debated assumptions that sex chromosomes do cause differences in such behaviors as rough-and-tumble play or interest in social interactions. As is the case with so many developmental phenomena, gender identity almost surely involves a rich interplay of biological influences (genetic and hormonal) and socialization. Here we have focused more heavily on the biological influences. In Chapters 14 and 15, we will focus more on socialization, although such socialization influences tend to involve gender roles as opposed to gender identity.

Q: How have views changed about the role of socialization in the emergence of gender identity?

It is important to keep in mind that gender identity is not the same as gender role or gender object choice. Categorizing oneself as a boy or a girl (*gender identity*) is usually associated with preferring activities and appearances that are correlated with that category (*gender roles*). In addition, sexual attraction to a particular gender category (*gender object choice*) is also typically correlated with an attraction to the opposite gender category. But each of these aspects of gender can be independent of each other. A boy can strongly identify as a male, prefer typically feminine things, and be attracted to girls. Every permutation is possible. For that reason, the development of gender identity is discussed in this chapter, while gender roles and attractions are discussed in Chapters 14 and 15, which deal more with social interactions and influences.

Q: What are the differences between gender identity, gender roles, and gender object choice?

Developing a Sense of Self-Worth

Beyond simply having a sense of themselves as individuals, children also develop feelings about their own worth and about their ability to accomplish goals. Over the course of childhood, they also improve control over their impulses and over the actions necessary to achieve their goals. During this time, children become more sophisticated interpreters of behavior, observing the effects of particular situations and individuals' dispositions to make inferences about themselves and others. This section explores these different facets of the self, which all bear on the question of how children's developing views of themselves relate to their behavior.

Self-Esteem

The child's self-concept and self-esteem are intricately intertwined, and it is difficult to discuss one without the other (Damon & Hart, 1982, 1988). As a first approximation, however, we can think of **self-esteem** as the value-related aspect of thinking about ourselves (Blascovich & Tomaka, 1991; Harter, 1998). In particular, self-esteem involves an assessment of our own worth and the emotions that accompany such an assessment. Self-concept, on the other hand, is a somewhat broader term with two major aspects. One facet of the self-concept is relatively judgment free and involves knowing facts about ourselves (*I am a boy. I live in Springfield. I like peppermint ice cream.*). The other facet evaluates aspects of the self, often by comparing ourselves to others (*I am the best runner. I am very smart. I am handsome.*). We will therefore consider the development of self-esteem in conjunction with the development of social comparison skills. If the younger child has only limited social comparison skills, then the kinds of social comparisons he is able to make should relate to the nature of his self-esteem.

Between the preschool years and adolescence, self-esteem normally undergoes several significant changes, which fall into roughly four periods (Harter, 1998). The first period, during the preschool years, involves excessively positive views of the self on all dimensions. These views are not only unrealistic, but also comically extreme at times. Who hasn't heard a 3-year-old boast that she is the strongest, fastest, or bravest person anywhere and that she can do anything? At these early ages, children ignore negative feedback that contradicts these inflated views of the self. This pattern seems to be related to their excessive optimism, discussed later in this chapter. It may be highly adaptive for the young child to overestimate her abilities so that she is not discouraged by the inevitable failures involved in becoming a more mature, skilled individual (Lockhart et al., 2002; Shin et al., 2007).

In the second period, during the early school years, the positive attitude remains but is not as extreme and unrealistic. Children around this age start to make social comparisons, mostly by comparing their current selves with the way they were at earlier ages (Oosterwegel & Oppenheimer, 1993; Ruble & Frey, 1991). Thus, a child might notice that she is now taller, stronger, or faster than she used to be. Conveniently, those comparisons to her younger self tend to reinforce a positive attitude about getting better and better (see Figure 13.7). Although some older accounts see the child as simply incapable of making other sorts of social comparisons in the early school years, the reality is more complex. At one level, preschoolers clearly make social comparisons, which can be evident in their jealousy when a peer has the object or approval they feel they deserve. But in the early school years, these social comparisons may not significantly affect the way the child views himself. That is, they may not lead the child to consider himself intrinsically worse than another child in some way—just deprived of something he deserves. Thus, the conscious sense of being deficient in comparison with others may not emerge until later, although it may be rooted in the same factors that induce jealousy. Similarly, even though 3-year-olds show shame at failing an easy task and pride in excelling at a hard one (Lewis et al., 1992), the effects of those feelings are limited to the situation at hand, not translated into a change in self-esteem.

In the third period, middle childhood, the child is able to break down her self-image into many components and evaluate each separately. As a result, she has a larger number of negative self-evaluations than in earlier years. During this period, social comparisons seem to more directly influence how the child values herself on various dimensions (Frey & Ruble, 1990). A child might observe, over several episodes, that he does not do as well as others at certain activities (for example, sports that involve large body movements such as running). Across these experiences, he may conclude that he is uncoordinated and that this is a trait-like property in him.

FIGURE 13.7 Change in self-esteem. Younger children are more likely to have high levels of self-esteem, which tends to drop with increasing age.

In the fourth period, during later periods of adolescence and young adulthood, social comparisons become more complex and context dependent. Adolescents learn to more carefully decide whom to compare themselves to, and their inferences about their own traits and dispositions become more refined. In addition, individual differences in interpreting social comparisons tend to become more pronounced during this period. Some now see their poor performances as evidence of enduring, unchangeable faults, whereas others view their weaknesses as areas where they need to devote more effort.

As Table 13.2 shows, self-esteem starts off unreasonably high and gradually becomes more realistic. As children enter adolescence, however, some characteristic ways of interpreting their own behavior (for example, believing that failure is due to stable, internal factors that affect all aspects of the self) may lead to the opposite extreme, resulting in unrealistically negative views of the self and low self-esteem. Those individuals can be at risk for serious depression (Bos et al., 2010; Buhrmester et al., 2011; Crocker & Wolfe, 2001; Harter, 1999).

As adolescents move into adulthood, self-esteem may appear to drop more than it really does. Some research shows that as people get older, they get better at the art of false modesty; that is, they learn how to act modestly even while maintaining a very high self-image (Baumeister & Ilko, 1995). This developing ability to manage public image must also be factored into many studies that involve changes in self-evaluations with age (Orth et al., 2011).

Period	Time of Emergence	Characteristics
1	Preschool years	Extreme positive views of self-esteem on all dimensions Related to preschoolers' general tendency toward excessive optimism Overestimates of abilities may serve an adaptive function by reducing discouragement when failures occur
2	Early school years	Still positive, but less extreme than in earlier years Begins to make social comparisons, but only by comparing to himself at younger age
3	Middle childhood	Begins to break down self-image into components Sees clear negative attributes in self Social comparisons begin to influence self-worth
4	Adolescence	Social comparisons become more complex Social comparisons depend more on context Individual differences in ways of interpreting social comparisons become more pronounced

TABLE 13.2 Developmental changes in self-esteem. As children grow older and engage in more sophisticated social comparisons, their level of self-esteem tends to drop from early overconfidence to a more realistic level, as well as becoming more intricately structured.

Q: How does the nature of children's self-esteem change from the preschool years to adolescence?

Self-Efficacy

Self-esteem is closely related to self-efficacy, a notion largely developed by the social learning theorist Albert Bandura (1977). **Self-efficacy** refers to people's beliefs about how capable they are of achieving their goals. It has a more moment-to-moment quality than self-esteem, as a person of stable, high self-esteem may, in some contexts, feel that she has little self-efficacy. When visiting another culture, for example, this person may realize how little she knows about its social norms and, consequently, how ineffective she would be at achieving immediate goals. Nonetheless, she may maintain high self-esteem because she realizes that this difficulty applies only to that local context. Similarly, a person of low self-esteem may have feelings of high self-efficacy in some circumstances, even if he does not act on his relatively limited or fragile confidence. This person might believe that he could easily play the lead in the school musical because he knows he can sing all the songs well, but he might not even try out because he feels that "losers" like him never get picked.

Self-esteem and self-efficacy are often tightly linked. One reason is the tendency to devalue or distance ourselves from those aspects of the self in which we have low self-efficacy. If, for example, someone who values athleticism discovers after many painful failures that he is unlikely to ever excel in most sports, he might have very low self-efficacy in that domain. Yet, if he devalues athleticism and comes to see it as irrelevant to his ideal self, this appraisal might not have much impact on self-esteem. Conversely, individuals trapped in a mire of low self-esteem may discount their areas of competence. Self-esteem tends to be global and domain general, while assessments of self-efficacy can be highly specific to tasks and contexts (see Figure 13.8).

FIGURE 13.8 Self-efficacy. Although feelings of self-efficacy can sometimes be exaggerated, such feelings are normally a more focused way of motivating behavior than much broader feelings of self-esteem.

This feature of self-efficacy has made it particularly interesting to clinical psychologists and educators. Because self-efficacy is more focused on specific situations, it has more potential for change than self-esteem, which tends to remain fairly stable across situations. Many psychologists believe that our self-efficacy can be powerfully shifted by the outcomes that we experience (Bandura, 1986). Imagine two individuals with the same initial appraisals of self-efficacy in mathematics and the same level of math ability. They could end up with very different feelings of self-efficacy if the first person attempts a very difficult problem and fails, while the second person takes on an easier mathematical task and succeeds. These results illustrate the usefulness of the concept of self-efficacy for teasing apart the related but distinct notions of self-esteem and true ability in particular areas. Only by realizing that self-esteem, self-efficacy, and true ability can each function and affect the self independently is it possible to account for behaviors.

One intriguing facet of self-efficacy is that it can change even without a direct experience of failure. Following other work by Bandura (1977), researchers have shown that when children observe peers (acting as models) experience success or failure, the peers' experiences can affect the self-efficacy of the observers (Schunk, 1987). This potential "contagiousness" of self-efficacy appraisals can be either unfortunate or encouraging. Imagine, for example, a girl in a classroom who observes two other girls whom she admires doing terribly on math tasks. If she identifies strongly with those girls, she might come away feeling low self-efficacy in math, even if she is very skilled in that area. If, however, she observes those two girls doing better at math than the other students, she might adopt related feelings of high self-efficacy.

The links between self-efficacy beliefs and behaviors also seem to become stronger with development. Young schoolchildren are more likely to have efficacy beliefs that do not strongly predict actual behaviors. As we will see later in this chapter, one reason for this disconnect arises from unrealistically high levels of optimism that young children often have about their current and future abilities. In contrast, older schoolchildren show a tighter relation between self-efficacy beliefs and behaviors related to those beliefs, and this holds across diverse domains. For example, compared with younger children who hold similar beliefs, older children who feel a higher efficacy about either their math ability or their ability to be aggressive are more likely to show higher levels of math achievement or aggression (Davis-Kean et al., 2008). Thus, programs designed to change self-efficacy beliefs may have greater consequences in older children.

In the end, the idea of self-efficacy is useful because it suggests a different type of intervention from those focused on self-esteem. The domain specificity of self-efficacy suggests that children who are doing poorly in one area should not be encouraged with broad statements about how wonderful they are. Specific praise is also likely to be less effective than actual *experiences* of self-efficacy. Even if praise can convince a child that he is highly talented in a specific area, that heightened self-esteem is fragile and can be shattered easily by experiencing a negative outcome. Instead, the most effective and beneficial way to intervene is to find a situation in which the child can experience a genuine, positive outcome and legitimately feel competent. For a child just beginning to learn a new skill, this approach would involve starting with relatively easy tasks in which success is likely (Bandura, 1997). This approach is similar to Vygotsky's ideas about how adults' supportive scaffolding and attention to a child's zones of proximal development can provide rewarding, hands-on learning experiences (see Chapter 9).

Q: Compare and contrast the notions of self-efficacy and self-esteem.

Self-Regulation

Along with the value-driven facets of the self, our sense of self includes our emotional states together with *self-regulation*—our ability to control our emotions and actions and behave in ways that are appropriate for various circumstances. Most parents and teachers would agree that young children do not always have their emotions under full control. Young children also have difficulty delaying gratification, even when doing so would pay off for them (see Figure 13.9). Older

FIGURE 13.9 Delay of gratification. Younger children have more difficulty delaying gratification, often because they are unable to use strategies to divert their attention.

DEVELOPMENT AND SOCIAL POLICY

Potential Drawbacks of Self-Esteem

The influence of self-esteem on behavior has become increasingly controversial in the realm of social policy (Twenge, 2006). For years, the conventional wisdom was that the more self-esteem that could be instilled or encouraged in children, the better. In addition, some argued that children from some disadvantaged groups might not be doing as well in school and on standardized tests because of lower self-esteem. Many schools in inner-city neighborhoods put enormous efforts into treating self-esteem problems under the assumption that raising self-esteem would solve problems of academic underachievement (Jackson, 2009).

Yet, the empirical data has not been so clear on the link between belonging to a disadvantaged group and having low self-esteem. An extensive analysis of 261 studies, which included a combined total of over half a million participants, concluded that self-esteem scores for African-American children were not lower, but actually slightly higher, than those for European-American children (Gray-Little & Hafdahl, 2000). In particular, compared with their European-American peers, African-American children under age 10 had slightly lower scores, while those over age 10 had higher scores. However, when children of all ages were taken together in a single comparison, the African-American children had higher self-esteem scores than the European-American children. This difference has appeared in subsequent analyses as well (Eccleston et al., 2010) and raises questions about whether efforts to raise self-esteem would be effective ways to close academic achievement gaps between disadvantaged groups and more advantaged groups.

In retrospect, these findings should not be that surprising. Children tend to compare themselves with the peers they typically encounter in order to build up norms on which to make a self-esteem judgment. Most African-American children are therefore going to compare themselves with other African-American children in the same situation. While far more African-American children live in poverty than European-American children (by some estimates the likelihood that an African-American child lives in poverty is almost four times greater (U.S. Bureau of the Census, 2010), that difference would not affect self-esteem judgments nearly as much as how well-off each child perceives himself relative to his immediate peers.

The strong influence of immediate peers is borne out by a related finding that wealthy African-American children who live in upscale suburban communities, typically among even more affluent European-American children, do tend to show lower self-esteem ratings than European-American children in the same communities, presumably because they are comparing their situation to their even more affluent neighbors (Gray-Little & Hafdahl, 2000). The implications of this research are complex. Group identification seems to help minority children's self-esteem when it focuses their comparisons on children living in similar circumstances. However, it can hurt their self-esteem when their group is juxtaposed with another group that is better off.

Contrary to earlier ideas, low self-esteem may also not be among the main reasons that some individuals transgress against society. Low self-esteem was, for a time, a popular

children often prey on their younger siblings' inability to delay gratification by dangling in front of them an immediately available toy or snack as an alternative to a much more desirable one that requires waiting. What 3-year-old can resist an older brother's offer of a pretty good toy that is here *now* in exchange for a much better one due to arrive by mail in a few days?

Self-regulation and the ability to delay gratification are recurring topics in this book. We saw early elements of these processes in infants in Chapter 7, and we also considered them in Chapter 12 in the context of how they might contribute to antisocial behavior. In this chapter, we want to focus on how the processes of self-regulation and the ability to delay gratification change over the course of normal child development. We will address how they are related to developmental changes not only in cognition and attention but also in the structure and functioning of the brain.

Many studies have examined which factors influence the ability to self-regulate and thereby delay gratification. In one classic study, 4-year-olds were asked which snack food they preferred: marshmallows or pretzels. The experimenters then told the children that they could have the less preferred food immediately, or if they waited for a longer time (up to 15 minutes), they could receive the preferred food (Mischel & Ebbeson, 1970; Mischel et al., 1972). Despite the relatively short wait time, younger children clearly had great difficulty delaying gratification, opting instead for the readily available, smaller gain.

One variable influencing the ability to wait was whether the children were left alone during the 15-minute delay explanation for why people "act out" against others; yet some of the most antisocial individuals, whether they are members of the Ku Klux Klan or violent killers, actually have unusually high self-esteem (Baumeister et al., 1996). Similarly, it used to be thought that bullies were driven by low self-esteem when in fact their self-esteem is comparable to other children's (Baumeister et al., 2005; see Figure 13.10). Low self-esteem undoubtedly has bad effects, but high self-esteem should not be considered uniformly positive. Indeed, in some cross-cultural comparisons, a high level of self-criticism, which would correspond to lower self-esteem, is often regarded as a positive personality trait because it encourages people to better themselves by addressing their faults (Heine et al., 1999). A more critical self-appraisal may be linked to an individual's viewing his traits as more modifiable, although the direction of influence here is unclear.

Actively pursuing higher self-esteem also generally has negative consequences. If people see certain aspects of themselves as crucial to their self-esteem and then try to ensure that they are doing well in those areas, they are likely to become frustrated and unhappy. Even when they do well, there is always a higher-level or a new, more impressive group to compare themselves against. Focusing directly on raising their self-esteem may cause brief increases in happiness, but not sustained ones (Crocker & Knight, 2005; Crocker & Park, 2004). Simply enjoying the process of developing an ability, without seeing it as essential to your worth, is much more likely to bring satisfaction. In addition, efforts to raise self-esteem to improve academic performance can backfire. In one study, college students experiencing academic difficulty actually did worse in their studies when their self-esteem was elevated (Forsyth et al., 2007). The researchers suggested that this drop in performance might have been because the weak students, in an effort to maintain or elevate self-esteem, actually reduced their academic effort.

FIGURE 13.10 **Bullying.** It has often been claimed that people who aggress against others, such as these school bullies, do so because they suffer from low self-esteem. But that claim seems to be mostly a myth, as such people often have higher levels of self-esteem.

In short, how people value themselves is certainly central to understanding behavior, mood, and motivation. Yet, the links between self-esteem and these facets of the self are more complex than previously thought. They involve the ever-growing ability to make social comparisons (both as an individual and as a member of a group), to believe that personal traits are changeable, and to use self-critical appraisals. The implications for social policy are correspondingly complex, calling into question any seemingly straightforward remedies based on raising self-esteem (Baumeister et al., 2003).

with the reward in front of them, which made it harder to resist immediate gratification than when the reward was not present. This result is not surprising; adults, too, are much more tempted by visible rewards. A subtler finding is that the ability to delay gratification may involve an attentional component that changes over the course of development (Mischel & Ebbeson, 1970; Mischel et al., 1972, 1973). As children grow older, they seem more able to direct their attention to things other than the immediately appealing object by focusing on either the other things in the room or various things in memory as a purposeful distraction. As adults, we use these strategies so automatically that we may not realize how common they are. (They are perhaps more obvious in attempts to deal with pain.) To overcome immediate impulses in favor of longer-term gains, children develop a wide range of strategies, from verbally reminding themselves of the long-term goal, to diverting their attention, to changing their attitude toward the various reward factors (Mischel, 1996).

A common method of distancing ourselves from temptation involves mentally replacing desired objects with symbols for those objects. In one study of this strategy, researchers showed 3- and 4-year-olds two piles that contained different numbers of jelly beans: a pile of three and a pile of eight (Carlson et al., 2005). They were taught that if they pointed at one pile, a puppet would get to take that pile, and they would receive the other pile. Although they clearly understood the instructions, the children had trouble learning to inhibit pointing to the pile that they wanted. They often pointed to the larger one and then unhappily received the smaller one for themselves. However, when the piles were replaced with symbols for larger and smaller amounts (for example, a picture of an elephant and a picture of a mouse) and the researchers explained the relationships between the symbols and jelly beans, the children could much more easily point to the mouse symbolizing the smaller amount in order to receive the larger pile. The symbols distanced the children from the temptation and allowed "cooler heads" to prevail over the immediate desire (Garon & Moore, 2007). The effects of symbols suggest that the abilities to inhibit responses and delay gratification are linked to both attentional abilities and the ability to use mental representations to regulate behaviors (Garon et al., 2008). This complex interplay of factors, some of which continue to develop throughout childhood, helps explain why the ability to delay gratification continues to improve gradually for many years after the preschool period.

Children show substantial individual differences in the ability to delay gratification. Some 4-year-olds could wait much longer than others for the snack they badly wanted. Interestingly, when the researchers followed up with those same groups of children more than 10 years later, they found that the ability to delay gratification at age 4 was correlated with many later aspects of cognitive and social behavior, including SAT scores (Mischel et al., 1989). Some researchers have also argued that a strong ability to delay gratification, or exercise "effortful control," as a toddler is a personality trait that remains stable for several years, and it manifests in such areas as having a stronger conscience (Kochanska & Knaack, 2003).

Q: How can strategies influence the development of self-regulation?

Brain Maturation and the Development of Self-Regulation

Along with the cognitive strategies for delaying gratification that emerge with development, there are good reasons to suspect that some patterns of brain maturation also contribute to this ability. When a child chooses to eat pretzels immediately rather than wait for the marshmallows she really wants, it may be because the child is unable to inhibit the desire for the pretzels long enough to wait for the larger reward. Whenever the notion of inhibition is raised, the brain's frontal lobes are potentially involved. As discussed in Chapter 2, the frontal lobes, which are part of the frontal cortex, lie behind the forehead at the front of the brain. Among their many capacities, one key role involves executive functions, the cognitive activities involved in goal-directed tasks and problem solving. These abilities allow us to optimize not just immediate payoffs but also long-term benefits (see Chapter 10).

One of the most famous cases in neuropsychology, which involved massive frontal lobe damage, began to reveal these structures' crucial contributions to self-regulation, especially emotional regulation. Phineas Gage, a 25-year-old railroad worker, was a victim of an unfortunate accident in 1848 in which a large iron rod entered his head at such an angle that it caused massive damage to the frontal lobes (see Figure 13.11). Quite remarkably, Gage survived the trauma and lived for 12 more years, but his personality had changed dramatically. He no longer seemed to have much control over his emotions; he had become impulsive and more prone to unnecessary risks. The injury impaired his ability to inhibit many aspects of his behavior. The relationship between frontal lobe damage and difficulties in self-regulation has been repeatedly documented for over 150 years (Heatherton, 2011).

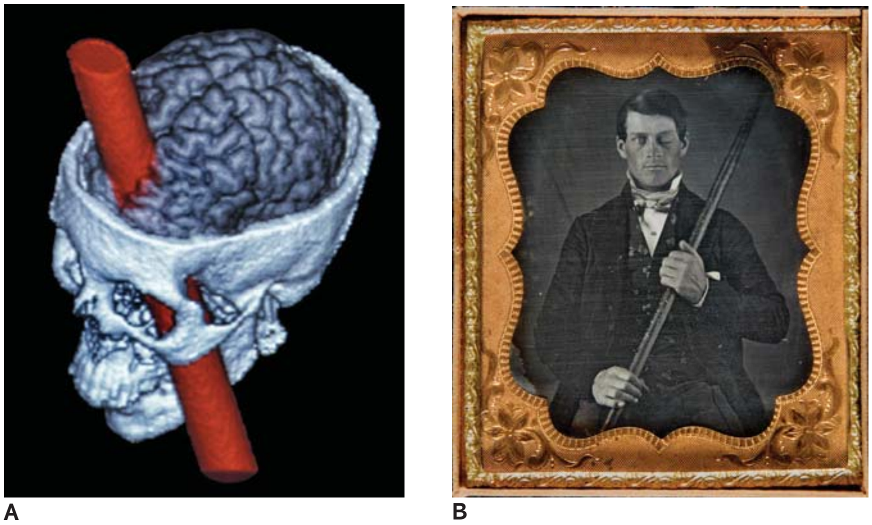

FIGURE 13.11 Damage in the frontal lobes and difficulties in self-regulation. **(A)** The metal spike that went through Phineas Gage's head is shown vividly in this diagram. The damage to Gage's frontal cortical regions caused profound changes in his ability to control his impulses. It has been argued that young children, who have frontal lobes that are less developed than the rest of their brain regions, are in effect developmental versions of Phineas Gage. They are subject to similar neurological deficits that cause difficulties in delay of gratification, impulse control, and planful behavior. **(B)** A photo of Phineas Gage.

In recent years, researchers have found intriguing evidence supporting a link between frontal lobe maturation and the development of self-regulation (Posner et al., 2012; Rothbart et al., 2011). One such study recorded event-related potentials (ERPs) occurring in children's brains as they engaged in tasks requiring self-regulation (Lewis et al., 2006). (ERPs are electrophysiological patterns of brain activity that can be monitored and recorded by electrodes placed on the scalp. Over the years, researchers have learned that specific ERP patterns are closely correlated with certain psychological events and can be used to infer when those events occur.) In this study, certain frontal lobe ERP patterns associated with inhibition declined with increasing age, decreasing in activation level in a manner that was closely related to improvements in self-regulation. It seems that older children become more efficient at inhibiting responses, allowing them to inhibit more effectively with less effort. This finding fits the common observations of experimenters and parents alike: Young children sometimes grimace with great effort to resist temptation, as many did in the pretzel-or-marshmallow task, but they often eventually succumb. Similarly, when children of the same age group (for example, toddlers) were studied, differences in the degree of self-regulation among those children were also correlated to measures of frontal lobe circuit activation (Morasch & Bell, 2011). For our purposes, it is important to note that the frontal lobes, as well as other associated brain regions involved in regulation of the emotions, are among the latest brain regions to mature (Heatherton, 2011; Sowell et al., 1999). As always, it is difficult to infer causal relations between behaviors and the many ways in which any brain area matures. However, it seems likely that the developing ability to regulate emotions and behaviors depends not only on learning but also on an increasing capacity for this kind of regulation as the frontal lobes and other brain areas mature (Garon et al., 2008; Posner et al., 2012; Rothbart et al., 2011).

Another provocative example of how biological factors are critical to the development of self-control comes from a study of two adults, both of whom had suffered substantial damage to the prefrontal cortex before they were 16 months of age (Anderson et al., 1999). Both were raised by middle-class, college-educated, married parents who seemed fully committed to supporting their children both materially and emotionally. Yet, despite these advantages, both adults had a long history of poor self-regulation. They regularly lied and stole, and, typical of patients with frontal lobe damage, had little concern for the future. They did not make plans or consider future events. Equally interesting was their apparent deficit in the expression of guilt or regret. This sort of pattern suggests that the development of self-regulation is linked to moral reasoning, not just moral behaviors.

As we saw in Chapter 12, one way to think about moral reasoning is as a cognitive system that develops but may not always be implemented because of difficulties in self-regulation. Another possibility is that difficulties in self-regulation could themselves influence the development of moral reasoning. If someone with poor self-regulation is not motivated to feel and engage with moral dilemmas, she may spend little time even thinking about them and instead simply act on her own desires. The two adults in this study also showed little empathy, a factor that would also limit their tendency to rethink or inhibit their actions out of concern for the suffering they cause in others.

Q: What are some biological factors that have been implicated in the development of self-regulation?

Contextual Influences on Self-Regulation

Self-regulation in young children can be modulated by the surrounding context in ways that are also seen in adults. For example, when a situation increases self-awareness, there is a tendency to show higher levels of self-regulation. An especially striking version of this effect occurs when people perform a behavior in front of a mirror. The mirror creates a feeling of self-consciousness and increases self-regulation in adults (Diener & Wallbom, 1976). The same mirror effect occurs in young children. For example, 3- and 4-year-olds showed higher levels of self-regulation (such as not looking in a box) when behaving in front of a large mirror than when the mirror was not present (Ross et al., 2011). Thus, contextual factors can have a strong influence even on young children who may have much more difficulty regulating their behaviors. Context is not a gradually "added on" modulator as development proceeds; rather, it is an important influence from an early age.

Context also bears on questions of school readiness and cultural variation. In earlier chapters, we saw several challenges to theories of cognitive development that argue for qualitative changes in concepts or reasoning. These challenges make such accounts difficult to use in arguments about school readiness. More plausible arguments may be made about self-regulation skills needing to reach a certain level of competence for children to thrive in schools (Blair, 2002; Blair & Razza, 2007; McClelland & Cameron, 2012). On average, it appears that at some point in the fifth or sixth year of life, most children have sufficient attentional flexibility (both staying on tasks and shifting as needed) and inhibitory control to be able to sit in a classroom and move through various tasks as the school day unfolds. These skills gradually improve to a threshold that is sufficient for success in the classroom and do not seem to represent a qualitative shift. Yet, children vary considerably in when they achieve such levels of self-regulation, with boys typically developing later than girls (Mathews et al., 2009).

There are many ways to measure the different dimensions of self-regulation, but one simple task, known as the Head-Toes-Knees-Shoulders (HTKS) task, offers an integrated assessment of many components of self-regulation, including attention, memory, executive skills, and impulse control. The task involves having children initially touch the body part mentioned with their hand. It then progresses to asking the children to touch "the opposite" body part (for example, the toes when the child hears "head" or the shoulders when the child hears "knees"). This second part of the task requires attention, working memory, and response inhibition—all components of self-regulation (McClelland & Cameron, 2012; Wanless et al., 2011). Moreover, the task is easy to use in real-world settings and predicts success in the classroom. In addition, it has been used cross-culturally and lends further support to findings of cross-cultural differences in the development of self-regulation skills. Research using the HTKS task has shown repeatedly that children from Asian countries tend to have higher levels of self-regulation early on than children from Western countries, such as the United States (Oh & Lewis, 2008; Sabbagh et al., 2006; Wanless et al., 2011; see Figure 13.12). The reasons for the cross-cultural and gender differences are unclear, but there are correlations with differences in socialization across the cultures. For example, teachers in Asian cultures tend to give more instructions concerning behavioral regulation (Lan et al., 2009). Thus, a child's local cultural context may help accelerate the development of self-regulation skills.

Our discussion of self-regulation has focused on the child's cognitive and emotional states and the interactions between them. These factors are critical for understanding how self-regulation develops, but it is in no way sufficient for a full understanding of self-control and moderation of children's behavior. Parents, peers, and the culture at large also affect how children internalize norms, attitudes, and ways of expressing emotions. These topics, however, are better discussed in Chapters 14 and 15, which deal with the influences of the family and of the larger culture.

Developing a Theory of Mind

In the course of a day of running errands, working, and interacting with family members, a typical adult makes many inferences about his own mind and the minds of others. Consider a middle-aged father arising at 6:00 a.m. As the alarm goes off, he wakes and momentarily considers what a strange dream he was having. His wife starts to stir, and he waits to ask her a question until she sits up in bed. He then asks her if she should pick up pizza on the way home that evening. She replies that she will be coming home early that day and will have time to do some shopping. He nods. Eating breakfast, he hears a radio commentator railing against a politician he has not heard of before. He assumes that the criticism is probably suspect. His teenage son sits down to breakfast and says, "Great, I love eating Brand X cornflakes five days in a row." The father acknowledges that he has been too busy to go shopping recently. Driving to work, the father notices a street sign that was struck by a car the night before and is now pointing the wrong way. He realizes that drivers who do

FIGURE 13.12 Cross-cultural differences in self-regulation. Numerous studies have reported that **(A)** 5-year-olds in Asian cultures have higher average levels of self-regulation than **(B)** 5-year-olds in North American cultures. Such differences may arise from differences in socialization practices.

not know the area will be surprised when they do not arrive at the destinations they intended. At work, he notices a coworker avoiding eye contact with the boss and assumes that person has just missed a deadline.

This example covers only the first few hours of the day, but this man has already revealed many facets of a mature theory of mind. That is, he has a well-developed set of untaught, intuitive beliefs about others' mental states and processes and an understanding of how to use those beliefs to infer others' goals to explain their actions. He can distinguish real from internally generated mental events such as dreams. He understands the cognitive differences between conscious and unconscious states. He knows why someone—in this case, his wife—would answer a question with a seemingly unrelated statement. Hearing the radio commentator, he uses a theory about how strong emotions can cloud judgment. He understands cues to irony or sarcasm and infers his son's true message. He realizes how a misplaced sign can cause false beliefs, with surprising results for those who act on them, and he knows how individuals who have irritated or disappointed someone typically act.

We make inferences based on our theory of mind so automatically that, much like our use of language, we often take for granted its complexity and sophistication. It may seem that there is no alternative to interpreting the social world this way. But consider the same morning from the perspective of someone who lacks a sound theory of mind. He wakes up wondering how he has suddenly, seemingly by magic, moved from being in a battle (his dream) to lying in bed. He immediately starts speaking to his wife, who is still groggy and misses most of what he says. When she awakens, he repeats himself, telling her to get pizza (asking is too subtle a concept, as it requires expecting the other person to consider the question and respond in a particular way). Her reply about coming home early mystifies him, because it is unrelated to pizza. Upon hearing the radio commentator, he assumes that the politician is bad. He is pleased to hear that his son likes Brand X cornflakes. He makes no inferences about the consequences of the reversed street sign, and he makes no assumptions about his coworker, whose behavior seems arbitrarily a bit different.

This second man is almost completely unable to make inferences involving beliefs, desires, and other mental events, not only in others' minds but also in his own. This scenario may seem far-fetched, yet some people with autism exhibit such cognitive deficits. And as mentioned in Chapter 6, some who have less extreme theory of mind deficits (among other differences) may be diagnosed with Asperger's syndrome, a related disorder on the autistic spectrum of developmental disorders (Baron-Cohen & Wheelwright, 2004; Klin et al., 2000). These individuals have tremendous difficulties negotiating the social world, even though they often do quite well in situations that do not require thinking about either their own minds or those of others. It is provocative to consider that both young children and autistic adults lack certain abilities to understand others' minds. Whether they share this behavior for the same cognitive reasons remains unknown.

We now turn to the question of how children develop a theory of mind. Building on topics from Chapters 5 and 6, we will start with a brief look at the early roots of theory of mind in very young children's inferences about social beings. We will then consider when and how children come to understand the consequences of holding false beliefs. These findings can help us address the question of whether theory of mind develops as a **module** (a relatively autonomous, specialized cognitive system) or whether this ability reflects the growth of a much broader cognitive skill, such as the ability to think about abstract representations of any kind. We will then consider the many ways in which the development of a full comprehensive theory of mind continues into late childhood and adolescence, involving forms of social understanding that go far beyond those measured by false-belief tasks.

Q: How is an intuitive theory of mind important for getting by in everyday life? Provide examples.

Early Aspects of Theory of Mind

As discussed in Chapters 5 and 6, even young infants treat social beings differently from nonsocial ones. They attend to eye gazes from other people in the first few months of life and become increasingly sophisticated at using eye gaze to infer another person's goals, perceptions, and mental states. For example, 9-month-old infants assume that eye gaze is an important cue to an object of interest. They will look longer at objects in locations that are in the direction of an eye gaze than at objects that are in the opposite direction from an eye gaze (Senju et al., 2008). They will even do so when the objects appear and reappear such that the objects are never on the screen at the same time as the face depicting eye gaze. Thus, the infants seem to be making inferences about what an agent is interested in, and they maintain such inferences over time. This ability in 9-month-olds appears to build on an earlier-developing, specialized neural circuit that responds to object-directed gazes. The brain activity of 4-month-old infants shows a distinctive pattern of event-related potentials (ERPs) when they are looking at someone else's object-directed gaze. This ERP pattern differs from the pattern measured when the infants are looking at a non-object-directed gaze (Hoehl et al., 2008). These results fit with the finding that adults show unique brain responses to gazes toward objects versus people (Pelphrey et al., 2003, 2004). Remember also that after 1-year-olds "interact" with a furry blob-shaped object that seems to respond to their vocalizations by beeping back at them, the infants will then make assumptions about gaze based on this semblance of a social interaction. When the blob then rotates toward one side, the infants will turn their heads the same way to see what the blob is "gazing" at (Johnson et al., 1998; see Chapter 5).

Many researchers are now investigating the early components of our ability to use relatively simple perceptual cues to make social inferences. As described in Chapter 5, by 10 months of age, children observing objects in motion interpret certain kinds of cues, such as self-propelled movement that seems to take into account changing conditions, as strong indicators of social agents with goals (Meltzoff, 1995; Woodward, 1998). A key question in these studies focuses on whether these early components form a critical foundation for a later, more complex theory of mind.

One proposal about the development of theory of mind suggests that the first step involves learning to attribute goals to other social beings (Leslie, 1994; Leslie et al., 2004). In this view, the learning process is driven by our interpretations of various perceptual cues, most notably direction of gaze (Baron-Cohen, 1995). In light of this possibility, it is interesting that humans are the only species whose eyes have dark pupils and irises against a clearly visible, bright white background, which makes discerning the direction of another's gaze much easier (see Figure 13.13 and Scientific Methods box). There may be some evolutionary cost if the whites of human eyes are more visible to predators, but the benefits for those who can more efficiently use gaze direction to infer others' goals may well be worth it (Tomasello et al., 2007).

By 18 months or so, infants begin to master the second step toward developing a full-fledged theory of mind. They become able to infer an actor's intention and imitate that goal rather than simply reproducing every action (Meltzoff, 1995). However, if they see cues indicating that the actor purposely chose an unusual or inconvenient way of doing something, such as turning on a light with his forehead even though his hands were free, they will imitate the precise action instead. If the actor's hands were full, they will imitate the goal (Gergely et al., 2002). The infants seem to infer that the hands-free actor must have chosen the more difficult action for a reason. (Chimpanzees also make this kind of inference while watching human actors in a nearly identical task, suggesting that this facet of the theory of mind is not unique to humans; Buttelman et al., 2007.) These are just a few of the various forms of evidence that indicate that well before age 1, infants make inferences that attribute rationality to social beings (see Chapters 5 and 6).

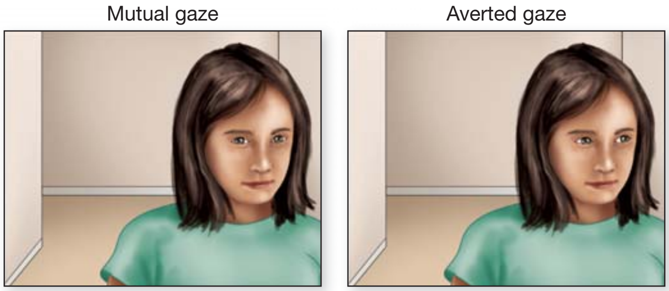

FIGURE 13.13 Direction of gaze. When participants watched a virtual person pass by who looked directly at them, they showed a different neural response than when the person's eyes were averted. These results suggest an early-emerging neural system specialized for processing gaze. Adapted from Pelphrey et al. (2004).

Comparative Perspectives on Theory of Mind

Just how much does a creature need to understand about the mind to be capable of rich social interactions? We know, for example, that many other species' social interactions go far beyond their mating and aggression rituals. Several primate species, for example, maintain elaborate **dominance hierarchies**, networks of social relations based on the ranking of group members. The structure of the hierarchy often involves a single powerful individual at the top and increasingly large groups of subordinates as social status decreases. These networks have powerful consequences for individuals and how they interact with one another (see Figure 13.14). More dominant members of a group usually have better access to mates, food, and shelter. When new members join a primate group, they are remarkably adept at observing interactions and inferring the whole hierarchy of relationships, such that establishing dominance relations with just one or two members allows them to know how they stand with everyone else. In addition, subordinate monkeys sometimes form coalitions that can change the group's power relationships, which implies a sophisticated understanding of rank and power (Barrett et al., 2007).

Considerable controversy remains over the extent to which the social reasoning skills of nonhuman primates psychologically resemble those of humans (Penn & Povinelli, 2007; Santos et al., 2007). Even the most sophisticated nonhuman primates, such as chimpanzees, sometimes fail spectacularly at tasks that seem to depend on social cognition. For example, Japanese and rhesus macaque monkeys will alert their offspring to the presence of a predator even when the offspring clearly knows about the predator already and the alerting call will put the parents at risk (Cheney &

SCIENTIFIC METHOD: Gaze Following in Human Infants and Great Apes

Hypothesis:

Because the whites of the eyes in humans are especially distinctive and can thus be used to detect where someone is looking, human infants will follow the direction of gaze as indicated by a person's eyes. On the other hand, great apes will rely more on the direction of the head as a whole.

Method:

1. Twenty 12-month-old infants, twenty 18-month-old infants, and nineteen great apes participated.
2. The experimenter "looked" at an object using only his eyes, his eyes together with his head, or his head with his eyes closed, or various controls.
3. The experimenter recorded the mean proportion of looks by the participants to the target.

Results:

Human infants looked at the target mostly as a consequence of where the experimenter's eyes looked, since the whites of human eyes make eye gaze direction much easier to discern. Great apes were influenced by both eyes and the head, but the head was more important.

Conclusion:

Humans from at least 1 year of age are especially skilled at using eye gaze direction to infer targets of mutual interest when in the company of another person. In contrast, great apes rely more on the much cruder, and potentially misleading, cue of head direction.

Source study: Tomasello et al. (2007).

The whites of human eyes make eye gaze direction much easier to discern.

		Age	Eyes	
			Yes	No
Head	Yes	12	0.20	0.06
		18	0.33	0.05
	No	12	0.09	0
		18	0.24	0.08

		Eyes	
		Yes	No
Head	Yes	0.53	0.35
	No	0.13	0.06

Great apes used head direction mostly.

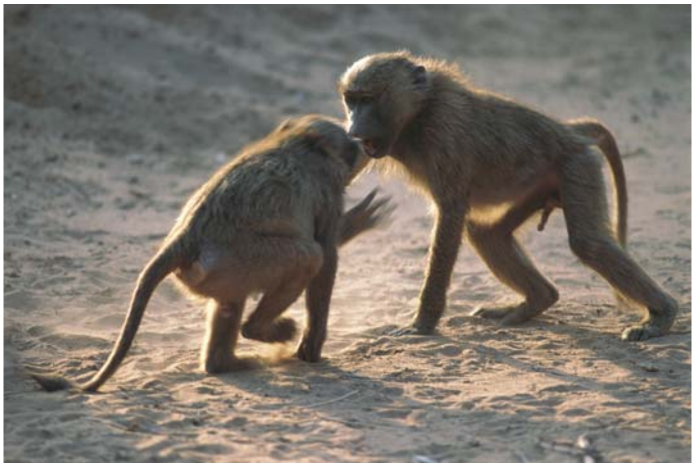

FIGURE 13.14 Social dominance and cognition. This juvenile rhesus monkey is showing a stereotypical expression of submission to an approaching dominant male. Primates can be very sensitively tuned to the social dominance relations that hold in quite large groups, performing what seem to be complex computations about others; yet they also can show glaring deficiencies in other theory of mind tasks.

Seyfarth, 1990, 1991). Similarly, chimpanzees will ignore gaze cues telling them where food is hidden, looking just as long at a container that a human is not looking at as at one that the human is staring at (Call et al., 2000).

But when primates are put into competitive situations, such as competing for food, they seem to show much more sophisticated forms of social cognition (Santos et al., 2007). In a situation where a known competitor can see one cache of food but not another, a chimpanzee will first get the food from the concealed location (Tomasello et al., 2003). In fact, across a wide range of competitive settings, several different classes of primates seem to take into account others' knowledge, using inferences about what their competitors are perceiving as a cue to what they know.

Do these successes in competitive circumstances mean that primates think about the social world in similar ways to humans? It is far too early to tell, but many researchers think that nonhuman primates' social understanding is likely to be more limited (Call & Tomasello, 2008; Tomasello et al., 2003). In particular, there may be some

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

Theory of Mind in Dogs?

Most research comparing social cognition in humans and other species has been with nonhuman primates, such as chimpanzees, gorillas, and various species of monkeys, since their genomes are most closely related to that of humans (chimpanzee DNA shares 96 percent of its sequence with human DNA). Yet, from an evolutionary perspective, it does not make sense as a research strategy. While primates vary dramatically in their degree of sociability—some species are loners and others are "groupies"—some nonprimate species are also highly social, sometimes in ways that are closely linked to human activities. It is especially interesting to ask how these other species—which do not share as many broad cognitive abilities with humans—might nonetheless have sophisticated social cognitive skills. Such a focus starts to reveal just how important general cognitive capacities might be to the development of social skills in humans (as opposed to more specific adaptations for social cognition).

Few groups are more appropriate for such questions than dogs (see Figure 13.15). Dogs started to differentiate from wolves roughly 15,000 years ago (Savolainen et al., 2002), and certain traits were selected for as these animals adapted to a special social niche with humans. Dogs may have been selected for their ability to partially perceive mental states in humans and work with them cooperatively rather than competitively in ways that maximize mutual benefit (Hare & Tomasello, 2005), and to excel at social as opposed to causal thinking (Brauer et al., 2006; Miklósi & Topál, 2012). Thus, although dogs do far worse than chimpanzees at using nonsocial cues to find the location of hidden food, they do better than chimpanzees in locating food on the basis of pointing gestures made by humans (Brauer et al., 2006).

Developmental studies have been particularly informative as to how dogs might differ from wolves. When dogs and wolves are both hand reared in equivalent socially rich human environments, young puppies show more advanced social cognition skills than young wolf pups. When hand-raised dogs and wolves were given pointing tasks, older wolves could use pointing cues to find hidden food, but younger ones (4-month-olds) could not, while 4-month-old puppies did just fine (Gácsi et al., 2009). Young dogs actually prefer human companions to other dogs, while young wolves do not (Morell, 2009). Dogs seem prepared to think more adeptly about social states, especially those in humans. Wolves can be gradually trained to be more social, but they do not seem to have the head start that dogs do.

There is active debate on just how rich a theory of mind to grant to dogs, but it does seem that they are adept at following eye gaze and sensing human goals (Miklósi & Topál, 2012). The fascinating question revolves around how simple the "seed" social cognitive skills need to be in young dogs to enable them to later be such adept social companions to humans. Answering this question will help us better understand what might be the minimal amount of social learning biases we might want to grant to human infants. It is impressive that higher-order social cognitive behaviors, such as the human tendency to "overimitate" the intentional acts of others (Lyons et al., 2011), are also found in dogs but not in apes (Miklósi & Topál, 2012).

FIGURE 13.15 Dog social cognition. Recent evidence suggests that dogs may have been selected for a set of specific perceptual and cognitive skills for detecting social information and intentions in humans, often in ways that exceed those found in great apes. These findings are important for understanding the origins of our own species' abilities to negotiate our social world.

Dogs and humans may also provide an example of convergent evolution of a set of social skills. Because dogs are in many ways more socially skilled and socially perceptive than most nonhuman primates, it seems that they developed these skills long after any common mammalian ancestor to both dogs and primates. Thus, they must have developed their social skills independently from those adaptations that humans may have acquired to be socially skilled. That convergence raises two questions: Have dogs adapted to the social niche in subtly different ways than human infants? Do dogs use different mechanisms than humans in developing social skills, or is there only one straightforward way to build social skills, such that both species independently evolved essentially the same building blocks of social cognition and perception?

limitations to how nonhuman primates think about beliefs. They may lack an ability to consider the beliefs of others across a wide range of situations where there are clear benefits to being aware of such beliefs, such as whether or not relatives are aware of predators; and they may have particular difficulties with understanding when others have beliefs that are not true reflections of reality. In more narrowly defined areas, such as competitive tasks, we may need to grant primates some notion of beliefs (Santos et al., 2007). At the least, those who do not want to grant beliefs to primates must come up with an alternative explanation of what mental processes make possible their success in competitive tasks.

In comparison with other primates, humans' more sophisticated abilities to think about intentions can sometimes lead young children astray. In one task, for example, both chimpanzees and preschoolers were presented with transparent containers that they had to manipulate to get at a desired object inside (Horner & Whiten, 2005; Lyons et al., 2007, 2011). The containers had several movable knobs and handles, only some of which were mechanically useful. Both chimpanzees and children watched an adult manipulate all of the knobs and handles, including the useless ones, before removing the object from its container. When the chimpanzees were then allowed to try to get the object out of the container, they omitted the unnecessary actions and efficiently removed the object, copying only the model's goals, not each action. In contrast, the children reproduced all the actions, including several blatantly unnecessary ones. Other studies have revealed that children who see an adult act on an object to achieve a goal assume that all the adult's actions must be causally relevant (Lyons et al., 2007, 2011). Thus, the children's sensitivity to the usual relationship between intentions and actions temporarily blinds them to the irrelevance of some actions. Complex social intuitions are an important part of understanding such cases where children "overimitate" (Over & Carpenter, 2013). The chimpanzees have no such problem.

In short, a rich body of evidence supports the idea that infants and young toddlers have some sense of the ways in which the goals and perceptions of social agents can influence those agents' actions. Furthermore, they seem to share many aspects of these abilities with other primates. Even some social nonprimates, such as dogs, can show surprising sophistication in some of these abilities (see New Directions box). Given this remarkable precocity, it is perhaps surprising that many researchers have also claimed that one central aspect of theory of mind, the ability to understand how beliefs influence behavior, may not be fully functional until well into a child's third year. These claims are based on a set of classic experimental tasks for investigating children's understanding of false beliefs.

Understanding False Beliefs

Normal adult functioning requires near-constant use of sophisticated capacities for thinking about other minds. Yet, researchers have repeatedly argued that young children have specific problems in thinking about some aspects of other minds. The most studied method for examining what children understand about others' beliefs has come to be known as the **false-belief task**. There are a number of variations on the task, all of which aim to assess a person's ability to understand how others might behave when they hold inaccurate beliefs (Wellman, 1990; Wimmer & Perner, 1983).

One of the most common false-belief tasks has been called the "Smarties task" (Perner et al., 1987), after a popular British candy similar to M&M's. The experimenter first shows the child a container with the familiar Smarties logo and asks what is inside. The child says it contains Smarties candy—but when the researcher opens the container, the child sees that it actually contains pencils. The researcher then asks what is really in the container, and the child replies, "Pencils." Up to this point, all children answer the same way, regardless of their age.

The child is then asked what another person seeing the container for the first time would think was inside of it. This question elicits very different answers depending on the child's age. Children who are approximately 3½ years and younger say that the new person would think there were pencils in the container. Children who are older than about 3½ respond like adults do, saying that the new person will think that the container contains Smarties (see Figure 13.16). Younger children do not seem to understand that beliefs do not simply mirror reality; rather, they represent a person's subjective understanding of reality (Cassidy, 1998; Perner et al., 1987). Consequently, they cannot see how someone could hold a belief contrary to what they, themselves, know to be true.

Hundreds of studies have documented younger children's apparent inability to understand the nature of false beliefs (Bloom & German, 2000; Flavell, 1999; Scholl & Leslie, 1999; Wellman et al., 2001). Some of them use tasks known as *unexpected contents tasks*, which closely resemble the Smarties task. Another type of false-belief task, sometimes known as *unexpected locations tasks* or "Sally–Anne tasks," after the best-known version, involves shifting objects to other locations. In this task, the experimenter verbally describes and visually depicts a person (Sally) who puts an object in a covered basket and then leaves the room. While Sally is gone, Anne enters, moves the object from the basket to a covered box, and leaves the room. Sally then returns, and the child is asked where Sally will look for the object (see Figure 13.17). Most children under age 3½ say that Sally will look in the box. Most children over 4 years of age say that Sally will look

Step 3 for a child at 3 years 11 months

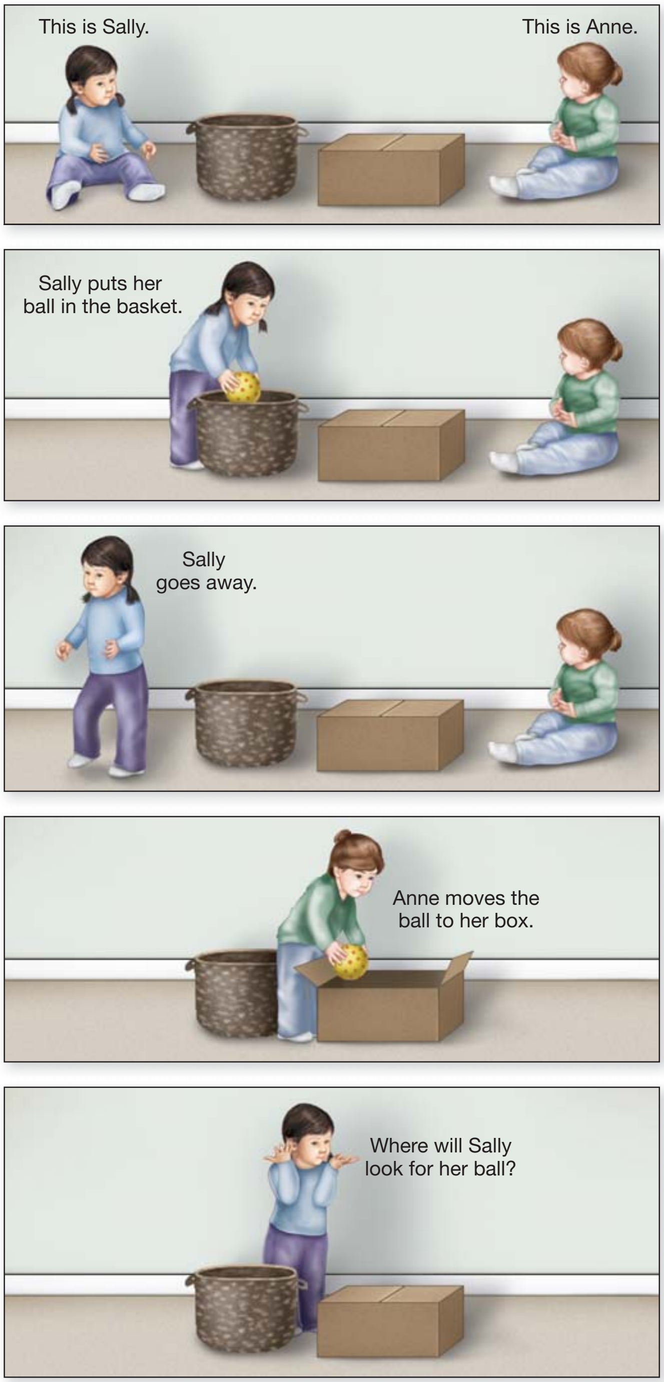
FIGURE 13.16 Understanding false beliefs. The Smarties task is one of several false-belief tasks in which children younger than between 3 years 6 months and 3 years 10 months tend to equate another person's beliefs with what is true in the world and not with their prior experiences and beliefs. The upper panels show a child who is 3 years 4 months first looking at a closed box of Smarties and then at an open box that says Smarties but contains pencils. In the lower panels, the child who is 3 years 4 months now thinks that another child would believe that pencils are in the closed box, but a child who is 3 years 11 months would think that another child would believe that Smarties are in the closed box.

in the basket (Frith & Frith, 1999). Thus, across the different types of false-belief tasks, children younger than about 3½ fail to see how a person's beliefs might cause them to act in a way that is contrary to the facts. These younger children seem to view human beliefs as if people were all-knowing (Barrett & Driesenga, 2001).

Q: Describe two different types of false-belief tasks.

How, then, do younger children understand beliefs if they are unable to see them as fallible? One proposal is that before about age 3½ children tend to think about beliefs as if they were desires (Wellman, 1990). To understand this frame of mind, consider that when we observe simpler animals, explanations based on drives (internal physiological states like hunger or thirst) are sometimes the most plausible way of explaining their behaviors. We do not think of a fly as having beliefs, but we can imagine it having something that might be construed as a desire in the sense of a drive or behavioral orientation toward reducing an uncomfortable physiological state or increasing a pleasant one. This kind of drive or "desire" is much simpler and more immediate than a goal-driven behavior. For example, a fly lands on sugary soft drink residue because it "wants" to eat sweet things. Of course, the sense of "want" that we attribute to the fly is not the same as our understanding of what it means for a 4-year-old to want another child's toy. In the child's case, we rely on our own mature theory of mind and assume that the child's wanting is associated with a rich set of beliefs about what the toy is like, who owns it, and what owning it would be like. On the other hand, a child who has not yet passed the false-belief task may not have that level of insight about the kinds of thoughts and feelings a playmate associates with wanting a toy and may see other people's behaviors in ways that more closely resemble how we see the fly.

Q: How might a 2-year-old's theory of mind be different from a 4-year-old's theory of mind?



This is Sally.
This is Anne.
Sally puts her ball in the basket.
Sally goes away.
Anne moves the ball to her box.
Where will Sally look for her ball?

FIGURE 13.17 **The Sally–Anne task.** Most children under 3½ years of age will say that Sally will look in the box. Most children over 4 years of age will say that Sally will look in the basket.

Evaluating the False-Belief Task At first glance, it seems that a failure to understand how false beliefs predict behaviors is an indication that a child has not yet developed a theory of mind. But there are troubling aspects to the false-belief tasks, leading some to suggest that it should be abandoned as a measure of the theory of mind (Bloom & German, 2000). Proponents of this argument offer two main criticisms of the tasks. First, succeeding at false-belief tasks may require abilities that have little to do with the theory of mind, such as a more general ability to inhibit judgments driven by salient knowledge. Thus, in the Sally–Anne task, children must inhibit their own knowledge of the object's true location and consider instead where the object might seem to be to another person.

This kind of inhibition has been studied separately in experiments that can perhaps shed some light on findings from false-belief studies. One example involves the **false-photograph task**. In this task, a child is shown a camera on a tripod with an object—say, a rubber duck—in front of it on a stand. The experimenter presses a button on the camera and declares that the camera has taken a picture. The duck is then replaced with a different object—for example, a teddy bear. The child is then asked what picture the camera took when the experimenter pressed the button. Three-year-olds had difficulty saying that the camera had taken a picture of the duck if the new object, the bear, was in front of the camera when the researcher asked the question (Zaitchik, 1990). Because reporting what happened with the camera does not require thinking about others' minds, this finding suggests that around age 3, children show a more general difficulty inhibiting responses driven by present displays. More precisely, young children's struggles with the false-photograph task seem to indicate that early on, it is difficult for them to inhibit a default response in which beliefs correspond to what presently appears to be true (Leslie, 2000; Leslie & Polizzi, 1998; Leslie et al., 2005). In most real-world situations, this is a good default strategy, since we usually think that our beliefs reflect reality (Birch & Bloom, 2007).

Other evidence supports the possibility that young children fail false-belief tasks, at least in part, because of difficulty inhibiting a default, present-oriented response. Older children with autism can pass the false-photograph task, but they fail the false-belief tasks intended to test for a theory of mind (Leekam & Perner, 1991; Leslie & Thaiss, 1992). Children with autism, like typically developing children, develop inhibitory skills that enable them to pass the false-photograph task. However, autistic children continue to have a specific deficit in thinking about beliefs. This pattern suggests that younger children without autism may fail false-belief tasks not because they cannot think about beliefs, but because of problems with inhibition common to all very young children. In sum, there are at least two possible explanations for young children's failures on false belief tasks. They may have less ability to inhibit a present-oriented response (a problem that is not specific to false beliefs), or they may have a problem thinking about others' false beliefs in particular.

The studies on children with autism raise the possibility that the developmental changes associated with passing false-belief tasks may be more associated with inhibitory abilities than with abilities to think about false beliefs per se. In this regard, it is interesting that the elderly, who show declines in executive functioning and inhibitory skills, can also show increased errors in the false-belief task—even though they clearly have not lost the ability to think about beliefs (German & Hehman, 2006). Other studies with children also support the idea that beyond issues related to theory of mind, some combination of deficits in planning, working memory, action awareness, and inhibition contributes to young children's failures on the false-belief task (Sabbagh et al., 2006a, 2006b).

The second objection to using false-belief tasks to measure theory of mind is closely tied to our earlier discussion about the ways that very young children think about social agents. In several respects, young children show at least some awareness and understanding of others' mental lives. In fact, there is some evidence that children may even show the ability to reason about false beliefs much earlier than age 3½ if the social reasoning is not embedded in a task that relies on verbal descriptions. In one study described more fully in Chapter 5, 15-month-olds saw an actor place an object in one location and then saw the actor go behind a screen, which blocked his view while the object was moved to a new location. When the actor returned and looked for the object in the new location, the infants looked longer than when the actor looked for the object where he left it (Onishi & Baillargeon, 2005). In a similar study, researchers showed 13-month-old infants animated movies in which a caterpillar-like creature either had visual information indicating the location of a hidden object or did not. When the creature had a visual cue, infants expected it to be more successful at finding the object (Surian et al., 2007). The nonverbal violation of the expected behaviors has also been used to show success by 2½-year-olds in both unexpected contents and unexpected locations tasks (He et al., 2011). Even in verbal tasks very much like the classic false-belief task, it is possible to get many 2½-year-olds to succeed if the experimenter looks up at the ceiling and seems to ask herself where the protagonist will look (He et al., 2012). In the classic task, when the experimenter looks at the child and asks the same question, 2½-year-olds will fail. Directly eliciting a response from the child seems to increase processing load and result in failure. More generally, the development of theory of mind and the ability to understand false beliefs now appear to develop in a more continuous manner after infancy and not as a dramatic qualitative shift at around 3½ years.

Further research is needed to know whether the infants are really thinking in terms of false beliefs or whether a simpler kind of understanding enables them to pass these tasks (Perner & Ruffman, 2005). Still, the fact that they can pass them at all makes the meaning of the original false-belief tasks less clear. One possibility is that the nonverbal violation of expectations tasks draw on a more implicit, nonverbal sense of the relationship between perception and knowledge, while the classic false-belief tasks tap into a more explicit, verbal sense of how beliefs can be at odds with reality (Sodian, 2011; Sodian & Thoermer, 2008).

Tracking of beliefs at a more implicit level has been found in infants as young as 7 months. For example, if infants see an animated agent watch an object go behind a barrier, they seem to automatically encode the agent's beliefs and, as a result, look longer when the object reappears in a manner that violates that agent's false beliefs (Kovács et al., 2010). Infants and adults alike seem unable to avoid encoding belief states of others and having those belief states influence their own responses to situations.

Well before children pass classic false-belief tasks, in some cases as young as 18 months, they can also reason about others' pretend play (Leslie, 1987b, 1992, 1994; Schwebel et al., 1999). The early emergence of this ability may seem surprising, since it, too, seems to involve reasoning about mental states that are contrary to reality. There is, however, a crucial difference between these forms of play and false beliefs. Pretend play does not require deliberately suppressing a belief about something that is true; rather, the game often involves making it clear to all players that the real object is not the same as the object it represents. The child who pretends to use a banana as a phone means for all to know that it is not really a phone, just a pretend phone. The pretend "belief" does not directly conflict with reality like the false belief does. Pretend play may therefore be one of the earliest ways in which children can think about alternative views of reality and be aware that those alternatives are mentally created.

Q: What are some limitations of the false-belief task as a measure of the child's developing theory of mind? What other factors might be influencing performance on the task?

A Theory of Mind Module?

Several theory of mind researchers have concluded that the ability to reason about the mental states of others is a special cognitive adaptation that was selected for in the course of evolution. According to these views, theories of mind do not simply arise from learning about the social world; they get a powerful head start from a dedicated cognitive system that is strongly influenced by our genes. This type of specialized mental system for understanding the beliefs and mental state processes of other people is sometimes described as a **theory of mind module** (**TOMM**). It is based on the proposal of philosopher Jerry Fodor (1983) that part of human cognitive makeup consists of specialized, autonomous systems for processing distinct kinds of information, such as spatial layout, syntactic structure, and number. Our abilities to reason about the minds of other people may be a module in the same sense (Scholl & Leslie, 1999). Such modules need not be present in fully functional forms at birth. They may take time to mature or may need certain environmental experiences to trigger them (Scholl & Leslie, 2001). In the debates about whether theory of mind constitutes a module, different scholars' meanings of "module" vary somewhat (Butterfill, 2007; Coltheart, 1999), creating challenges in comparing their claims.

The most prominent issues revolve around two main questions. First, does theory of mind constitute a separate cognitive domain—a cognitive system tailored for one kind of information? Second, do theory of mind abilities show informational encapsulation—that is, is the module influenced only by other information that is processed within the module (Fodor, 1983)? This latter question is based on the idea that once a module begins to process information, its operations are not influenced by other external information. Informational encapsulation is an appealing explanation for optical illusions, in which, for example, you cannot help but see that one line is shorter than another despite knowing that they are identical in length. Some argue that theory of mind functions similarly, as a domain-specific, informationally encapsulated module (Scholl & Leslie, 1999). One form of evidence for this possibility resembles the optical illusion example. If circles and triangles moving about on a screen appear to "interact" in certain ways, most people cannot help but interpret them as animate, social agents, as if their movements trigger a theory of mind module. We saw in Chapter 5 how even quite young infants seem to have similar social agent inferences triggered by simple geometric forms.

The proposal that theory of mind abilities form a module is perhaps most dramatically illustrated by the specific deficits of some individuals who are diagnosed with autism (see Figure 13.18). Autism is a developmental disorder marked by language problems and extraordinary difficulties with social interactions. Yet, some autistic individuals also show normal proficiency or even exceptional skill in other cognitive domains, including math, music, drawing, or reasoning about complex devices. Even so, the same person who excels at some cognitive tasks may still fail at false-belief tasks (Baron-Cohen, 1995). By contrast, some individuals without autism may not do as well on cognitive tasks but may pass false-belief tasks easily. This pattern is compatible with the claim of a biologically determined distinct system for processing beliefs and other sophisticated aspects of mental lives—processing that can be notably difficult for people with autism (Leslie, 1994; Leslie & Thaiss, 1992). This claim is compelling to the extent that the difficulty with beliefs is bounded (that is, confined to that one sphere) and most evident in socially rich environments where other children would develop complex understandings of others' minds.

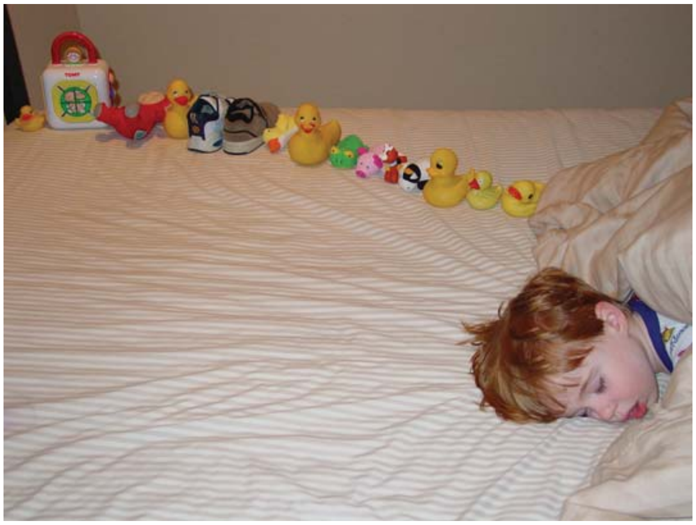


FIGURE 13.18 Autism and theory of mind. Although this child diagnosed with autism may show meticulous attention to objects and their relations, such as making this neat ordered progression of ducks, the same child may have great difficulty thinking about the mental states of other people, a deficit that some researchers construe as evidence for a theory of mind module.

The idea of a theory of mind module is controversial, however, and other scholars believe that it may be possible to explain the sense of social agency in simple animations, the autism findings, and related phenomena in other ways. In this view, there is no module for thinking about beliefs. Instead, this ability emerges from a combination of lower-level perceptual abilities and higher-level, domain-general cognitive mechanisms (Stone & Gerrans, 2006). In particular, there may be dedicated neural systems for processing gaze, processing vocal intonations, and recognizing emotions. All this perceptual information could then feed into a domain-general set of cognitive mechanisms. One frequently emphasized domain-general skill known as *meta-representation* is concerned with the ability to understand and think about the sense in which a representation—like a mental image or an idea—stands for something else. Understanding representations at this level is necessary for understanding beliefs. A critical question for future research is whether theory of mind tasks require the same meta-representational skill as other kinds of tasks unrelated to thinking about beliefs.

Finally, any discussion of the modularity of theory of mind must also consider the correlation between poor language skills and autism. The implications of this correlation are unclear, in part because as a child develops language skills and theory of mind, each ability can influence the other. That is, some aspects of language acquisition, such as the ability to learn words, may be intimately related to the ability to think about the mental states of other people (Bloom, 2000; see Chapter 8). At the same time, language development may help foster a more sophisticated theory of mind. For example, developmental changes in the ways that children use verbs about mental states, such as "think" and "know," correlate with success on traditional false-belief tasks (Astington, 1993, 1999; Bartsch & Wellman, 1995). Children may have to master these verbs and the syntactic constructions they require in order to reason more explicitly about false beliefs (de Villiers & de Villiers, 2000). As research on both directions of influence are understood in more detail, they will inform the debates about whether there is a theory of mind module.

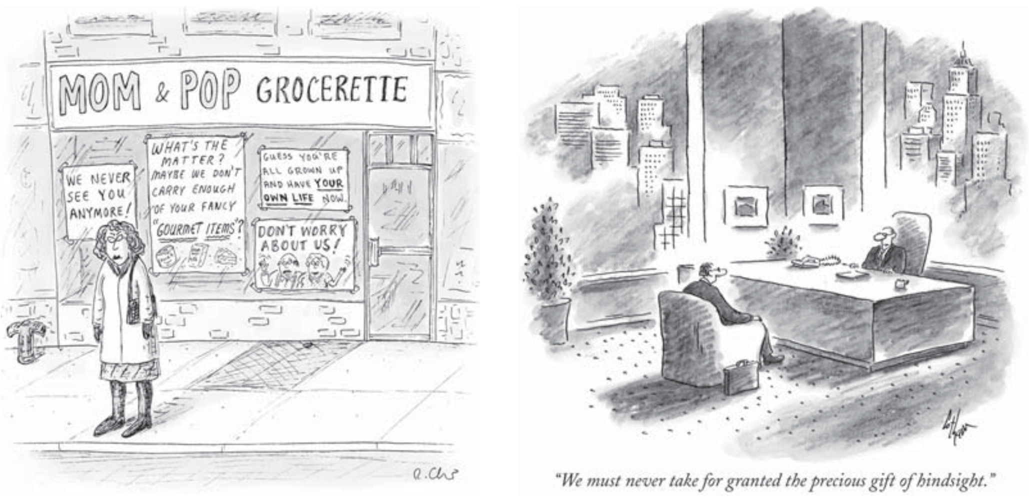
Beyond False Beliefs

Beyond the study of false beliefs, much remains to be understood about theory of mind development. As mentioned earlier, it is clear from studies of infants and animals that both are capable of specialized reasoning about social entities, and this reasoning occurs in infants long before they can succeed on the standard false-belief task. It is also clear that much of this social reasoning may occur automatically, which makes the "theory" part of "theory of mind" a misnomer. (We do not describe the processes of object perception as requiring a "theory" of three-dimensional objects.) Indeed, if theory of mind functions largely automatically, as an informationally encapsulated module, it becomes less theory-like.

At the more sophisticated end of the developmental continuum, the ability to reason about others' minds is certainly not complete when the first explicit false-belief task is solved. A host of other, later-emerging cognitive skills support more nuanced social inferences, and there are correspondingly complex false-belief tasks that children solve only at later ages (Perner & Wimmer, 1985; Stone et al., 1998; Wellman & Liu, 2004). Later in this chapter, we will look more closely at some of these more advanced social skills, such as the ability to make attributions about behaviors in others and in ourselves.

Like false-belief tasks, certain kinds of humor—which do not necessarily involve false beliefs—can reveal the limits of children's abilities to make inferences about states of mind. It is not uncommon to see a bright 10-year-old staring at a cartoon or comic strip without understanding why it is funny. To be sure, humor is sometimes based on adult knowledge that the child simply has not acquired. But sometimes the child is mystified because of missing insight into the nuances of social interactions and others' mental states. Consider the cartoons in Figure 13.19. The idea of a "guilt trip" that a parent might put on a child involves complex inferences about both parties' beliefs, goals, and conflicting internal states. Similarly, the silliness of the "precious gift of hindsight" is based on understanding that it is always easier to speak authoritatively about the recent past than about the future. Humor, one of the least understood of human behaviors (Provine, 2000), very often involves sophisticated reasoning about the mental states of others.

Theory of mind is also critical to sharing information. Almost all forms of communication are incomplete and rely on the two parties' assumptions about their common ground of understanding (Clark, 1996). For example, when I tell someone that there is a bathroom on the second floor, we both immediately assume a rich arena of unstated common knowledge (I mean the second floor of the building we are in; I mean a bathroom that is working; if we are in



MOM & POP GROCERETTE
WE NEVER SEE YOU ANYMORE!
WHAT'S THE MATTER? MAYBE WE DON'T CARRY ENOUGH OF YOUR FANCY "GOURMET ITEMS"?
GUESS YOU'RE ALL GROWN UP AND HAVE YOUR OWN LIFE NOW.
DON'T WORRY ABOUT US!
"We must never take for granted the precious gift of hindsight."

FIGURE 13.19 Humor and theory of mind. In both of these cartoons, relatively subtle aspects of our beliefs about other minds are needed to see the intended humor. These examples serve to illustrate how theory of mind skills continue to develop long past middle childhood and suggest that the developmental patterns seen in toddlers should perhaps be seen as part of a much longer continuum of developmental change than as the a critical period in which a mature theory of mind emerges.

public, I mean different bathrooms for men and women). Likewise, using and appreciating human artifacts, whether they are books, signs, or art, critically involve thinking about the creator's goals, beliefs, and desires. The simplest acts of communication would be incredibly difficult without a rich theory of mind that helps us to decide what the speaker likely knows already and what is new. Full mastery of such communicative nuances takes many years to develop (Birch & Bloom, 2004; Matthews et al., 2007).

Making Attributions about Ourselves and Others

Closely linked to the ability to infer another person's goals is the ability to attribute or ascribe particular reasons for behaviors. This, too, is a critical part of understanding people's actions. If the person in front of you in line is impatient with the cashier, is he generally a rude, inconsiderate person, or is he just running late? More generally, how and when do we interpret someone's behavior as evidence for what kind of person he is? We make similar attributions to explain past experiences and to predict how we and others might do on future tasks. Furthermore, the nature of those predictions changes over the course of our development. In addition, our attributions about our own behavior, including why we engage in certain activities, seem to strongly influence how we go about them and how much we enjoy them.

Emerging Explanations of Behavior

Most people engage in particular actions either because of some intrinsic fact about them (they love chocolate) or because of some degree of environmental pressure (they want to be like their friends who love chocolate). We can all recognize both kinds of factors, but most Western cultures tend to overemphasize **dispositional factors**, those influences on behavior that have to do with a person's intrinsic nature, at the expense of equally important **situational factors**, aspects of a situation that influence the way a person acts. Thus, a researcher might be able to show empirically that performance on a math test is influenced by both situational variables (noise, anxiety, and fatigue) and dispositional variables (math ability, motivation, or speed of processing). Nonetheless, when most Westerners observe someone else doing poorly or well in math, they are much more likely to attribute the failure or success to internal, dispositional variables than to situational ones. This bias in observing others is known as the **fundamental attribution error** (Ross, 1977; see Figure 13.20).

Interestingly, this bias does not occur to the same extent across cultures, occurring more frequently in individualist cultures than in collectivist ones. (As described in Chapter 12, individualist cultures consider the rights and autonomy of the individual to be paramount, whereas collectivist cultures place more value on the rights of the group and the connections between people.) Members of individualist cultures more often attribute a person's behavior to dispositional factors—aspects of her personality or disposition. On the other hand, members of collectivist cultures tend to

FIGURE 13.20 The fundamental attribution error. The fundamental attribution error leads people to **(A)** attribute negative behaviors in others to internal trait-like dispositions but **(B)** the same behavior in themselves to situations. Researchers have asked how the relative emphases on dispositions and situations change with development.

understand behaviors as arising from situational factors—aspects of the specific circumstances or situation (Brewer & Chen, 2006; Miller, 1984; Nisbett, 2003; Oyserman & Lee, 2008; Peng et al., 2001). Social psychologists refer to the study of the theories people use to explain their own behavior and that of others as **attribution theory**. Indeed, one of the originators of attribution theory, Fritz Heider, referred to it as the study of "naive psychology" (Heider, 1958).

How do these different aspects of attribution develop? Early researchers suggested that younger children tend to take a situational view of behavior and only switch toward a dispositional view with increasing age (Higgins & Bryant, 1982; Ruble et al., 1979). But these claims were made before the strong cross-cultural differences were known. It now seems much less plausible that a dispositional orientation is the mature, adult state, since we know that the majority of adults in the world do not end up with that orientation.

More recently, many studies have shown that children do not uniformly use situational attributions. For example, in one study, children ranging in age from 4 to 7 years of age were told about an individual's traits and asked to predict that person's behavior (for example, "Sally is really mean. Will she share her cookies?"). By at least age 5, the children could use the trait information as evidence to predict behavior (Yuill & Pearson, 1998). We saw in Chapter 12 that when children reason about moral decisions or guilt, they sometimes focus exclusively on the situation and neglect the mental states of others, especially if the scenario is described in a way that does not emphasize mental states. However, the tendency to neglect those internal or dispositional factors in moral decisions unless they are made salient does not amount to an *inability* to think about them.

In fact, even young children sometimes assume that other people's internal qualities help explain their behaviors (Gelman, 1992, 2003; Gelman & Wellman, 1991). For example, a child who repeatedly observes a friend's room in disarray might conclude that the friend is a messy person. That sort of *essentialist bias* toward explaining a person's behavior in terms of his unchanging, inner essence seems to suggest that children would rely too much on dispositional factors early on, something that is also claimed to contribute to some forms of prejudice. Thus, young children will sometimes assume that if a person with a different skin color than her own does something wrong, the tendency to do things wrong may be intrinsic to everyone with that skin color (Hirschfeld, 1996).

Q: How do young children's attributions about others' behavior differ from those of older children and adults? How might these developmental patterns vary across cultures?

The observation that young children can use trait information to explain behavior raises the interesting question of whether they use this information in the same way as older children and adults. **Trait-based reasoning**, which is more common at older ages, is a nuanced way of considering individual qualities or traits in relation to specific circumstances. For example, a good person's trusting nature may make him overly gullible, which could lead to reckless or harmful behavior in some situations. In this way of thinking, traits themselves are not necessarily good or bad; the outcome depends on the situation. In contrast, research suggests that younger children are more likely than older ones to use **evaluative reasoning**, which involves viewing a person as entirely good or bad, and predicting his future behaviors based on that view (Alvarez et al., 2001). Someone who engages in evaluative reasoning may notice a specific trait, such as selfishness, and then evaluate the person as wholly good or bad based on it (see Figure 13.21). When 5- and 6-year-olds were compared with 9- and 10-year-olds, the younger children were much more likely to rely on broad, evaluative judgments in predicting behaviors and to be less attentive to trait-specific ones (Alvarez et al., 2001). This tendency in young children may also shed light on the earlier idea that they do not consider dispositional factors. Some traits, such as being shy or outgoing, are relatively free of evaluative components. If a young child is primarily using evaluative reasoning, she might find it more difficult to use these neutral traits to predict behavior.

While evaluative and trait-based reasoning may seem like qualitatively different types of understanding, a more conservative interpretation is that simplified versions of trait-based reasoning may be as salient as evaluative ones. Young children may be most aware of the global, evaluative aspect of traits, and perhaps attend to it first, because

FIGURE 13.21 Evaluative versus trait-based reasoning. When preschoolers make attributions and judgments about others, they may have a tendency to make more global evaluative judgments than more trait-specific ones.

it suggests some very simple, useful behavioral guidelines, such as avoiding people with "bad" traits and interacting with those who show "good" traits. Thus, developmental changes may reflect more intrinsic complexity of some attributions than it does a qualitative shift. There are indeed subtle traits that lead to complex behavioral predictions that may escape a young child, but there are even subtler aspects of traits and their expressions in situations that can similarly elude many adults. If you observe someone behaving shyly on a date, you would be hard-pressed to predict whether he would be shy about giving a speech. Indeed, we may underestimate how often as adults, especially in times of stress, we gravitate toward the same holistic, evaluative attributions. This tendency is related to the fundamental attribution error, in that both involve an essentialist bias. But they differ in that evaluative reasoning involves characterizing someone as entirely good or bad based on a particular trait, whereas the fundamental attribution error involves relying too much on dispositional factors (which need not be especially positive or negative) to explain behavior.

If younger children are sometimes able to reason about specific traits, why did the earlier studies suggest otherwise? One possibility is that even though the children understood the traits, they may have struggled with the way that the traditional experimental tasks asked about links between traits and behaviors. In many older studies, the child would hear a description or watch a video of an individual doing something. A researcher would then ask the child to choose which of two other behaviors was more likely for that person based on the first one. For example, a child might watch a video of a boy sharing a toy (a trait-relevant behavior). Then an experimenter would ask the child whether the boy was more likely to help a friend clean his room or not help and just stand by idly. In these studies, children often would not make correct inferences until age 8 or older (Rholes & Ruble, 1984).

These sorts of tasks, however, require a more complex reasoning process than a single trait-based prediction of behavior. The child has to make an inference from one behavior to a trait (from sharing a toy to kindness) and then link that trait to a second behavior (helping clean a room). But what would happen if the task were broken into two parts: one that requires making an inference from a behavior to a trait and another that involves making an inference from a trait to a behavior? And would children's performance improve if the trait-behavior relationships were made clearer and more salient, perhaps by providing several example behaviors for each trait? With these methodological changes, even 4-year-olds can easily reason about specific traits (Liu et al., 2007). Therefore, what develops may not be an ability to think about specific traits as much as an ability to combine behavior-to-trait inferences with trait-to-behavior inferences. This ability may be supported by the child's language development as she improves at using labels for traits (Liu et al., 2007). It also seems that when children are thinking about personal attributes in areas where they are particularly well practiced (such as figuring out which adults are the most expert informants about how to label things or which adults give the clearest instructions), they can make quite focused attributions about reliable versus unreliable informants without extending such attributions in a more global, evaluative manner (Einav & Robinson, 2011; Fusaro et al., 2011; Jaswal et al., 2010; Lutz & Keil, 2002).

Q: What is evaluative reasoning, and what is its purported role in the development of the ability to make attributions about others?

Although recent evidence calls into question the earlier claims that children simply describe behavior and neglect internal states, it is difficult to discern an overall developmental pattern in terms of when (and whether) children show a dispositional or a situational bias. Thus far, researchers have used very different methods to examine how children make attributions at different ages. As a result, it is difficult to generalize across studies to say whether children start with either a situational or a dispositional bias and how their attributions change depending on the culture around them. The most conservative interpretation of the research at present is that at least by the age of 5, and possibly quite a bit earlier, children can take into account both situational and dispositional factors in their attributions. It is possible that infants and toddlers show no early bias between the two styles before adopting the one that prevails in the surrounding culture. To see how attributional differences across cultures develop, we need a more systematic set of studies that uses similar methods but controls for possible age effects on how children make attributions.

Beyond situational versus dispositional biases, children at least as young as 5 years of age take into account how traits emerge when they make inferences about traits and evaluate individuals with those traits. For example, in one set of studies, children were told about traits that emerged in individuals either naturally, through sustained effort, through extrinsic rewards, or through artificial medical enhancement. Even though all traits were manifested to the same extent in the described individuals, children tended to see the naturally emerging traits as persisting over longer time periods and under more challenging conditions. In addition, they evaluated those who acquired traits naturally more positively than those who acquired them through extrinsic means or through some kind of medicine (Lockhart et al., 2013). This bias for naturally emerging traits therefore appears early and persists into adulthood; and it represents one way in which the causal story of a trait's emergence influences subsequent inferences and evaluations about that trait. Even young children do not simply evaluate a trait in terms of its current surface characteristics; they are strongly influenced by information about how that trait originated.

Traits and Optimism

Your view of yourself clearly influences your view of your future. If you believe you are a powerful, competent person, you are inclined to think the future bodes well for you. If you see yourself as helpless and incompetent, you will more likely believe that uncontrollable events are in store and that you will not manage them well. Two key questions help frame these issues with respect to development: (1) Are there any general patterns concerning how children at different ages view the future? (2) What kinds of individual differences develop among children in this respect?

Regarding general developmental patterns, younger children seem to be more optimistic about the future than older ones (see Figure 13.22). In one set of studies, each child was told about another child of his or her same sex and age who had a negative attribute that was either physical (such as an allergy) or psychological (such as being messy) or a blend of the two (such as being physically aggressive; Lockhart et al., 2002). Table 13.3 shows several sample attributes. The child was then asked what the child in the story would be like at various times in the future, up to young adulthood. Even the youngest children expected more positive change in psychological attributes than physical ones. But remarkably, they also expected that the physical traits, some as permanent as a missing finger, would dramatically improve in the future.

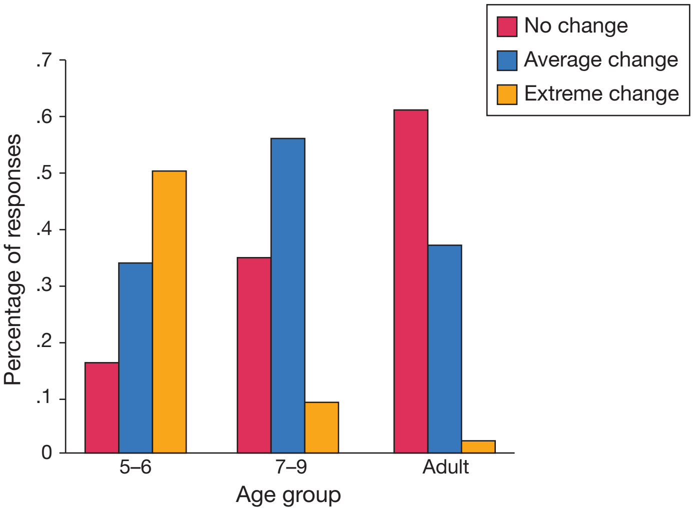

FIGURE 13.22 Younger children as more optimistic. There is a dramatic developmental change between kindergarten and second grade in the extent to which traits are seen as changing in a positive direction with increasing age. Adapted from Lockhart et al. (2002).

Type of Negative Trait	Examples
Biological	Missing finger Allergy
Blend of biological and psychological	Aggression Attentional problems
Psychological	Messy Fearful

TABLE 13.3 Youthful optimism about negative traits. This table shows the three types of negative traits that children and adults were asked about in the study of children's optimism about the future. The younger the child, the more likely he was to see negative traits as likely to improve. Adapted from Lockhart et al. (2002).

This youthful optimism reflects a positive attitude toward others' traits and presumably toward their own, since the protagonists were of the same age and sex as the participants. Younger children's optimism may help protect them from getting discouraged by the inevitable failures that come from being unskilled in so many areas (Lockhart et al., 2002). Interestingly, a study comparing young Japanese children's and adults' responses to the same type of stories about children found the same general pattern as in the original U.S. study: the Japanese children showed much more optimism about improvement of negative traits than did the adults (Lockhart et al., 2008). However, the Japanese data suggested a somewhat different developmental trajectory, in which Japanese adults tended to be more optimistic about some scenarios than were American adults.

This research reveals that young children can be quite sensitive to others' traits and can differentiate between different types of traits. They also tend to see negative traits as more likely to eventually change for the better. As children grow older, this optimism starts to fade, and in middle childhood, individual differences in attributional style become more prominent. As we will see in Chapter 16, the children who become most pessimistic may also struggle with depression in adolescence (Cole et al., 2008).

Alongside these general developmental patterns, children's individual differences in optimism and attributional styles have become a major area of research in their own right. The most prominent view describes two contrasting ways that children come to regard their own traits and consequently their prospects for future success. The first type of children, known as **fixed-trait theorists**, think of their traits as unchangeable, or fixed, aspects of themselves. If they fail at something, they assume they must be permanently deficient in that area. The other type of children, **incremental theorists**, see their traits as changeable with enough work. They therefore may have a more positive view of the future and be more likely to sustain their efforts (Dweck, 1986, 2006, 2012; Dweck & Leggett, 1988). Given the finding that younger children are more optimistic than older ones about traits improving in the future, we can view younger children as tending toward incremental theories and, in some cases, developing fixed-trait theories in middle childhood. It seems likely that the children who shift toward fixed-trait attributions do not change their attributions for all traits across the board. However, the specificity of those changes still needs further research.

Q: How do young children differ from older children in terms of their optimism about traits? Why might such a difference exist?

Attribution, Motivation, and Creativity

Although children who develop a fixed-trait attribution style tend to be more pessimistic about the possibility of self-improvement, they do not necessarily maintain an unalterable level of self-esteem. In fact, the nature of fixed-trait attributions can be changed somewhat by valuing the traits differently. Thus, simply praising a group of schoolchildren for doing well on a task *because of their intelligence*, which emphasizes a fixed trait, instead of praising them for doing well *because of their efforts*, can reduce their intrinsic motivation for the task. Emphasizing a fixed trait this way may make the possibility of failure much more threatening—since failure could then reflect a fixed lack of intelligence rather than an easily addressed lack of effort. Such trait-oriented feedback may unintentionally encourage children to choose rote, easy tasks in which success is virtually guaranteed (Dweck, 2006; Mueller & Dweck, 1998). Moreover, if a child views a particular negative trait that he possesses as fixed, he may give up on developing skills related to that trait. Such differences in attributional style have been used to explain why some children give up when faced with failure, while others persevere (Dweck, 2012; Dweck & Leggett, 1988).

A related effect involving attributions about motivation does not arise from individual differences; instead, it reflects ways in which all children—and, in fact, people of all ages—can have intrinsic motivation and even creativity undermined based on attributions they make about themselves. A set of landmark studies vividly demonstrated this effect by showing how a previously enjoyable activity can come to seem like a chore (Condry & Chambers, 1978; Deci, 1971, 1972; Lepper et al., 1973; Lepper & Greene, 1975).

At the outset of one study, all the children in a preschool classroom were given some new play materials: a set of magic markers and some drawing paper (Lepper et al., 1973). The researchers pointed out the markers and paper to the children and then measured how long each child spent playing with the markers compared with the other available toys. Children who showed some intrinsic interest in drawing by playing with the markers for more than a certain amount of time were selected for the experiment. They were then randomly assigned to one of three conditions: the expected-reward condition, the unexpected-reward condition, or the no-reward condition.

Each child was then taken individually to a separate room. Children in the expected-reward group were shown an ornate certificate called a “Good Player Award” and told that they would receive it if they helped the experimenters by drawing pictures for them. The children in the unexpected-reward and the no-reward conditions were simply asked to play with the materials and draw some pictures. In all three conditions, the children were given the same amount of time to draw. Children in the expected-reward condition were all given the expected award for playing well. Children in the unexpected-reward group were told, after they had spent their time drawing, that because they drew so well they were going to be given a “Good Player Award” (which was identical to that in the expected-reward condition). Finally, children in the no-reward group were returned to their classroom without any mention of rewards. A week or two after these one-on-one sessions, a new group of researchers, who had no information about which experimental condition each child had experienced, observed the children drawing with markers in the classroom, just as they had when their intrinsic interest was first assessed. Figure 13.23A summarizes this procedure.

This study’s findings, which are summarized in Figure 13.23B, are impressive. Children in either the unexpected-reward condition or the no-reward condition played with the materials more than they had at the outset. In contrast, the children who drew pictures for the expected reward showed a marked drop in spontaneous play with the drawing materials. This drop has been explained in terms of several factors that blend ideas about the self with attributions about a person’s own motivation. More specifically, after the children in the expected-reward condition heard about the “Good Player Award,” they apparently came to attribute their own interest in drawing to the expectation of being rewarded for it. Attributing their behavior to that extrinsic factor (the reward)

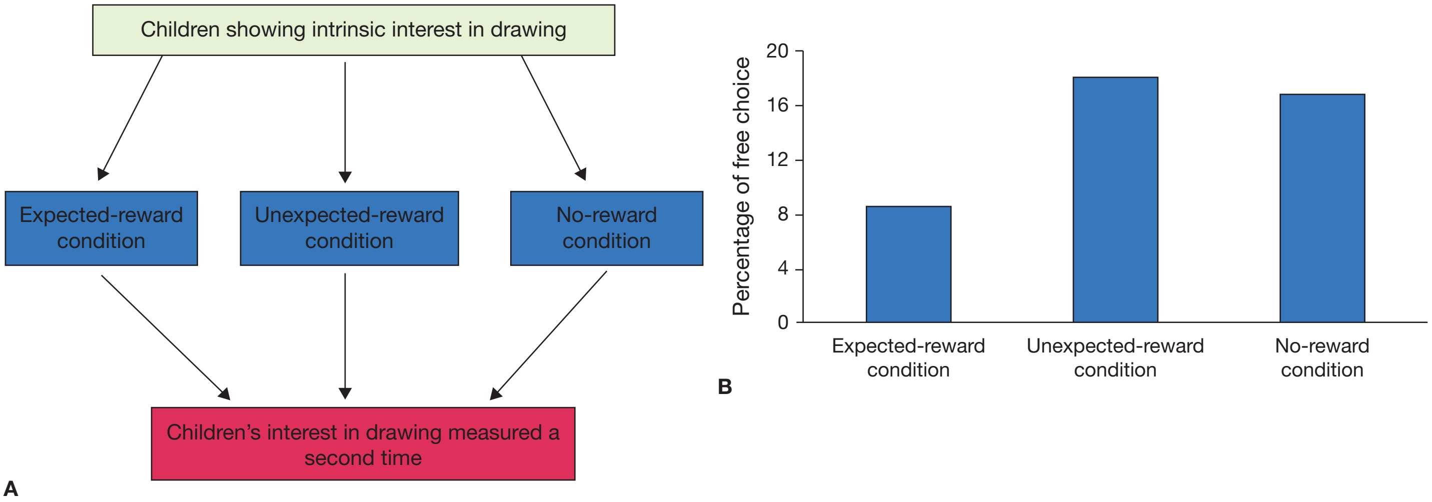

FIGURE 13.23 The effects of reward on intrinsic motivation. (A) The 1973 study by Lepper and colleagues assigned children to three distinct groups and then used a common assessment to determine the percentage of time that children later chose to play with toys that they had played with during the experimental session. **(B)** This bar graph shows the mean proportion of time that children chose to play with the target activity in postexperimental sessions. Adapted from Lepper et al. (1973).

made them discount their earlier, intrinsic motivation for it, a phenomenon called the **overjustification effect**. After drawing to earn the certificate, they seemed to say to themselves, "I was doing this because I knew I'd get a reward, not because I liked doing it." Thus, their self-concept mediated the way the reward influenced their behavior.

Later studies have shown that if a child simply knows that an adult is carefully watching her behavior, it can be enough to reduce intrinsic motivation for the behavior (Lepper & Green, 1975). In at least some situations, a child who knows she is being monitored may reframe the situation in such a way that she believes that her behavior is motivated by an external factor. Even the simple act of praising a child's actions can have a similar effect, undermining motivations for those actions (Henderlong & Lepper, 2002). Yet, not all praise has negative effects; praising internal factors like effort, rather than actions, is less likely to decrease motivation.

These kinds of interactions and individual responses are cognitively complex. The child must assess her own mental and motivational states, take into account the context in which she is acting, weigh the external conditions influencing her actions, and then reassess the relationships between the situational and dispositional factors that drive her behaviors. Thus, the presence of the overjustification effect in preschoolers suggests that they clearly can take into account both situational and dispositional factors when interpreting their own behaviors.

One of the most insidious ways that extrinsic rewards can influence self-perception and motivation comes from how children change their approach to a task when the rewards are still present. In the example of drawing with markers, if the children who initially expected (and received) a reward for drawing were later asked to draw to earn a reward, they tended to make a larger number of drawings that were of lower quality. Some children even set up little assembly lines to churn out lots of drawings that were each much simpler than the ones they produced before being rewarded. This new approach to the task fit their interpretation of working for the reward (Loveland & Olley, 1979).

Nonetheless, some have argued that extrinsic rewards need not undermine creativity if they are handled carefully. These researchers suggest that if you fine-tune the system to reward only high-quality work and explicitly convey this criterion, the rewards can enhance creativity (Eisenberger & Cameron, 1998). Yet, these manipulations can be subtle and difficult to implement with young children. In the long run, the rewards may still subtly undermine motivation and creativity if they are removed. For example, one study on educational video games that teach mathematical skills found that games designed around intrinsic motivational factors (such as embedding math problems in the most exciting parts of the games) were seven times as likely to be played in the future as those that were designed around extrinsic factors (such as embedding math problems in tests at the end of the game, where achieving a good score was the reward; Habgood & Ainsworth, 2011).

In research that rewarded children with stickers for eating vegetables they disliked, the studies reported an increased preference for the rewarded vegetables more than 3 months later (Cooke et al., 2011). The success may be because the vegetables were initially strongly disliked, and by being rewarded for eating them, the children learned that they were not so bad. On the other hand, if the children's initial dislike for the vegetables had been mild, the result of reinforcement could have been negligible. Thus, when there is less of an initial negative bias, it may be harder to instill a shift toward the more positive.

The findings that external rewards, mediated by children's self-perception, can undermine intrinsic motivation strike a clear blow to behaviorist models of learning. According to the behaviorists, reinforcing a behavior in any organism, whether it is a human or a rat, should increase the propensity for the behavior. Yet, the drawing studies (and many other studies that followed) showed the opposite pattern. Although some have contended that this large set of studies was flawed and have argued that the effect does not exist (Eisenberger & Cameron, 1996), more recent, extensive analyses strongly indicate that these overjustification effects are real and substantial (Deci et al., 1999; Lepper et al., 1999, 2005). These interactions may be far more complex than originally envisioned, and it may be possible to craft effective, beneficial patterns of external reinforcement by attending carefully to the child's mental states. Most interesting, however, is the evidence that the overjustification effect provides rich social cognitions that influence behavior, even in the preschool years.

In practical terms, this research shows that extrinsic rewards should be used with caution in educational and other structured settings. Extrinsic awards extend far beyond the classroom to include medals for athletic competitions, prizes for artists, and salary bonuses in the workplace. In a broader sense, the critical issue seems to be giving people the sense of having a choice in decisions about their lives and daily activities, or what is sometimes called **self-determination** (Ryan & Deci, 2000). If people feel that they have had an important role in determining their behaviors, they will be more motivated to engage in those behaviors. This effect seems even stronger in children, for whom tangible rewards seem to have the most negative consequences (Patall et al., 2008). The importance of choice, however, also suggests ways to mitigate the negative effects of rewards. For example, if people are given a choice among several rewards, that element of choice can often reduce the feeling of being coerced by the reward (Patall et al., 2008; see Figure 13.24). Thus, introducing a genuine opportunity for choice and self-determination into a reward system, such as allowing children in a task to use their "earnings" to choose which of several rewards to purchase, can often mitigate the negative effects of rewards and can sometimes maintain their positive effects on immediate performance.

A second practical issue concerns whether the harmful effects of extrinsic rewards might vary across cultures and groups. It has been reported, for example, that extrinsic motivations may be less detrimental in some non-Western settings, such as China, where conformity to group norms is often valued more than autonomy (Iyengar & Lepper, 1999). But a closer look suggests more commonalities than differences in this respect between Western and Chinese children (Bao & Lam, 2008). For example, if Chinese children have strong social and emotional connections to those providing rewards, their negative effects are somewhat reduced. However, when there is no such close connection, the rewards tend to decrease intrinsic motivation, just as they do in the West (Bao & Lam, 2008). One interpretation of this finding is that the Chinese children have internalized the goals and needs of those to whom they are closely attached, such that the intrinsic motivation of someone like a parent is, by extension, their own intrinsic motivation. This view suggests that children in the West might also be insulated from the negative effects of extrinsic rewards if they see the reward givers as part of their own close-knit, supportive group, such as a family with strong shared values and goals (Bao & Lam, 2008; Lepper et al., 2005).

FIGURE 13.24 Choice among rewards. When children are given a choice among rewards, the choice can reduce the degree to which intrinsic motivation is undermined.

Q: Describe how it is possible to turn play into work, even for preschoolers. What mechanism seems to explain this transformation?

Conclusions

The ability to understand our own mental states and those of others is an essential part of being a mature person. Contrary to earlier views, it seems that young children and even infants do have some sense of self, but it may be based largely on their perceptions and actions, without involving conceptual or autobiographical ways of construing themselves. Each of these senses of self have early versions, or competencies, that become more sophisticated over time, again supporting a recurring theme in this book of the value of focusing on emerging abilities as opposed to disappearing deficits. In addition, the different facets of the self interact and support growth in each other over the course of development. Thus, an increasing sense of the private self supports the development of the extended self, and the conceptual self interacts with the autobiographical self. In fact, there are interactions between almost every pairing of the dimensions of self that reinforce each other and that may ultimately help create a more integrated sense of self.

In the development of self-esteem and self-efficacy, which add an evaluative component to self-knowledge and understanding, we see once again how basic cognitive skills influence a child's social interactions and emotional states. Contrary to popular accounts, however, low self-esteem may not be the prime cause of various acting-out behaviors, and overly high self-esteem can pose its own set of problems. Thoughts about the self are also related to emotional intelligence and self-regulation. The ability to regulate ourselves by deferring gratification may heavily involve attentional skills that enable us to focus on other objects rather than the most salient goal. Self-regulation ability is also influenced by context: whether those influences are local, such as the presence of a mirror, or cultural, reflecting the way a culture values strong self-regulation skills early on. In this way, we see that self-regulation can be amplified or reduced by the environment in which a child develops.

The child's understanding of other people's minds shows several major developmental changes. Based on the much-studied false-belief tasks, earlier researchers believed that children younger than about 3½ cannot think of others as having false beliefs about a current situation. But more recent studies suggest that young children's failures on false-belief tasks tell only part of the story of how theory of mind develops. More recent research is beginning to link simple patterns of goal attribution in infancy to more complex patterns of thought about second-order beliefs in late childhood. It is therefore misleading to think that there is a particular age at which a child acquires a theory of mind. Instead, it makes more sense to think of infants and young children as using a rich array of cognitive and perceptual tools to gain insight into the behaviors of social agents. Even an understanding of false beliefs now seems to be within the conceptual reach of infants, at least at an implicit level. Again, emerging competencies is a powerful theme. Younger children and infants do not have as many of these tools, and they use some of them in more limited ways. Nonetheless, they are sensitive from a very early age to some special properties of social agents, and they benefit from ways in which all these tools work together to help them think about the minds of others.

A critical part of thinking about others involves inferences about dispositions and traits and how they might vary or stay the same over time. Children, much more than adults, tend to believe that negative traits in younger people will improve and that positive traits will endure. This youthful optimism may be a way of protecting themselves against the failures that younger children inevitably experience as they mature. These attributions are critical, as well, to understanding motivation and creativity in the young child. More broadly, these developmental patterns and the related idea of self-determination reinforce the theme that for optimal development, children need to be active agents in their own developmental journeys and not just passive recipients of environmental inputs and contingencies. Of course, external inputs and encouragement are important, but they should always occur in ways that are sensitive to a child's intrinsic interests and curiosities.

STUDY AND REVIEW

SUMMARY

Self-Concepts and Self-Representations

- In the first few years of life, there are dramatic changes in how children come to view themselves. These changes are best understood by realizing that there may be at least five distinct senses of self that emerge at quite different times and in different ways: the ecological self, the interpersonal self, the extended self, the private self, and the conceptual self.
- An important dimension of knowing ourselves is gender identity, a form of knowledge that may be far more subject to biological constraints than was originally thought. The sense of gender identity, however, is quite distinct from culturally provided sex roles, which can vary independently, as an individual can firmly believe that he or she has a certain gender while engaging in many roles typically associated with the other gender.

Developing a Sense of Self-Worth

- Self-esteem, a sense of our own value, changes dramatically during childhood, generally progressing from extremely high views of the self to more realistic assessments based on increasingly complex social comparisons.
- Self-efficacy, the belief about our capacity to achieve goals, is a more focused kind of assessment often tied to a particular situation. Feelings of low self-efficacy are often easier to change in a child than low self-esteem.

Self-Regulation

- Younger children are more likely to show difficulties in self-regulation and hence have problems in delaying gratification. Difficulties may frequently arise from inadequate strategies for diverting their attention from a desired object or from an inability to think of ways to make the desired object less salient or accessible. Some of these problems may arise from relatively late maturation of regions of the frontal lobes. Damage to these regions in adult brains can also cause self-regulation problems. Self-regulation levels vary across both genders and cultures. They seem to be influenced by surrounding cultural and local contexts as well as socialization practices.

Developing a Theory of Mind

- Young children are certainly aware of the distinctive nature of social beings, but at first they may understand other social beings' behavior only in terms of their goals and desires.

  Even after young children come to explicitly appreciate that others have beliefs (usually around 2 years of age), it isn't until about 3½ years of age that they stop having difficulty reasoning about other people having *false* beliefs. The ability to understand false beliefs is not the same as having a full-fledged theory of mind, but it is an important component. At a more tacit level, however, and in tasks that pose lower loads on executive processing, even infants may have rudimentary senses of false beliefs.
- There is some evidence that nonhuman primates can grasp a rudimentary sense of others' false beliefs, although this kind of understanding may become uniquely rich and nuanced in humans.
- These patterns raise questions about whether the child's theory of mind develops as a cognitive module that is domain specific, informationally encapsulated, and strongly determined by biological factors. Some proponents of a theory of mind module have proposed that disruptions in the development of theory of mind skills may underlie some forms of autism.

Making Attributions about Ourselves and Others

- The ability to make attributions that explain others' behaviors is critical to functioning as a social individual. Younger children have rudimentary attributional skills, but they often seem to miss the subtler connections between traits, situations, and behaviors. They may be more likely to use evaluative reasoning, making global evaluations of others as good or bad and missing the more subtle aspects of how traits can predict behaviors.

  Younger children show greater optimism than older children and adults, leading them to believe that negative traits change for the better as people age. This optimism may have adaptive value if it shields the child from discouragement when she faces failures associated with being young and inexperienced.
- Attributions about the self can powerfully influence motivation and creativity. Even for preschool children, an intrinsically interesting form of play can become much more like work if they perceive that they are doing it merely to earn external rewards.
- It is possible to motivate children without undermining intrinsic motivation. This can be done by reminding children of the intrinsic values of their actions as well as enabling feelings of choice and control when using more external forms of reinforcement.

THOUGHT QUESTIONS

1. We have seen that people have at least five distinct senses of self that emerge at different times in the first few years of life. To what extent do you think these different senses of the self start to become integrated into a more unitary sense of self as a child grows older? If you do think such an integration occurs, speculate on how it might happen. If not, explain why you think the senses stay separate.
2. How might an extremely low level of self-esteem have very different consequences for a young child, a schoolchild, an adolescent, and an adult?
3. Describe a situation in which a typical 7-year-old would fail to reason adequately about the mental states of others, but a typical 16-year-old would succeed. What is different about the cognitive capacities of the two age groups that would explain the failure of the younger child and the success of the teenager?
4. An elementary school has been using extrinsic rewards in an attempt to motivate its students to achieve at higher levels in mathematics. The program is not working well, as the students are starting to regard mathematics as unpleasant work. The school is not willing to stop using the rewards but asks you for advice on what else they might do to diminish the negative side effects of the rewards. What do you recommend?

Conclusions

Summary

When Bill Clinton rose to prominence on the American political stage, people naturally wanted to know about his family background. When attention turned to his younger half-brother, Roger, it seemed that Roger could not be more different from Bill (see Figure 14.1). Roger had drifted from job to job, and his career as musician never got off the ground. He became increasingly involved in drug use, which in turn led to drug dealing. For these activities, Roger served 2 years in prison. Meanwhile, his brother Bill earned a scholarship to Georgetown University, then a prestigious Rhodes Scholarship to Oxford. He attended Yale Law School before returning to his home state of Arkansas, where he was elected governor at age 32, making him the youngest governor in the country. After nearly 12 years as governor, he was twice elected to the presidency of the United States.

Given such dramatically different outcomes for these two boys born to the same mother, many people assumed that the sharp contrasts in their lives must have been caused by their different fathers, presumably because of different genetic predispositions. Others pointed to birth order and argued that Bill Clinton, being the firstborn, was bound to be less rebellious and more driven to achieve. In fact, developmental studies that consider large numbers of families tell a more complicated and more interesting story (Conley, 2004). For example, one major influence on children appears to be the economic status of the family as a whole. When a family is wealthy, siblings tend to turn out more alike. When a family is poor, as was the case with the Clintons, parents have to choose how to allocate their limited resources, often devoting most of them to the child who shows the earliest promise, which is frequently the firstborn. Because there are many other possible sources of influence, we cannot know for sure whether the Clintons' economic situation contributed significantly to the differences between Bill and Roger, but we do know that these effects are much more common in less advantaged families. As this chapter describes, the family is a site of numerous interacting influences on development, from socioeconomic and cultural factors, to the effects of parents and children on one another, to the consequences of sibling relations, to the importance of shared genetic predispositions.

FIGURE 14.1 Sibling differences. Even though they grew up in the same family and have a physical resemblance, Bill and Roger Clinton had markedly different life courses. Recent research is beginning to offer explanations for why siblings turn out to be similar or very different.

For most of us, the most important social unit in our lives is our family. We explain our preferences in relation to family traditions (either aligned with them or against them); we relate powerful, formative family experiences, from moments of shared understanding to horrific fights; and we refer to our family role, such as the scapegoat, the leader, the joker, or even the black sheep. We do these things because we assume that many aspects of who we are can be understood in terms of what our family is like. In this chapter, we will consider how the many facets of the family contribute to a child's development. We will start with views of parenting, then consider siblings, and finally explore how changes, conflict, and physical and psychological abuse in the family might be understood in light of the wide range of possible influences that can arise between the child and the other members of the family.

Studies on families employ an enormous range of methods, many of them quite different from the experimental approaches encountered in earlier chapters. To study the effects of parents on children, of children on parents, or of siblings on each other, it is not often feasible to experimentally assign groups of children to different parenting conditions. Instead, researchers usually have to examine interactions in real families as they unfold. They then infer causal patterns from the intricate networks of correlations between family members' behaviors, their personality traits, and many types of family environments. Striking correlations often emerge, but it is difficult to uncover an unambiguous causal pathway or cycle that explains those correlations.

It is important to keep these methodological challenges in mind as we address several questions about families. First, we will focus on the parents and ask how different kinds of parenting can influence a child's development. For example, does a rigid and overly controlling style of parenting tend to affect children's personality traits, perhaps by making the children more submissive? We will also consider how different contexts, whether cultural or socioeconomic, can interact with the effects of different kinds of parenting (see Figure 14.2). We will ask about other possible causes of correlations between parental behaviors and those in their children. In particular, we will discuss research regarding children's effects on their parents, effects of shared genotypes

FIGURE 14.2 Parents and families. Throughout the world, families are considered the primary social unit of a child's life and where many of the strongest emotional bonds are formed. It is therefore not surprising that families, and parents in particular, have been thought to be the primary agents behind a child's personality and value system. That view, however, has become highly controversial, as other factors beyond the family are shown to have influence as well.

between parents and their children, and the effects of different environments on both children and their parents. We will also explore how all of these factors interact in contributing to long-lasting characteristics in children.

We will then consider the relations between siblings, including whether a child's position relative to other siblings has a systematic effect on development: Does birth order matter, and does it matter more in some kinds of families than in others? We will also examine whether siblings try to differentiate themselves from one another. And we will consider the other social and cognitive effects that sibling relationships may have on the children themselves and within the family system.

We will then turn to the developmental consequences of changing family demographics. In the United States and many other developed countries, the trends in recent decades point toward older parents, smaller families, and more families in which both parents work full-time outside the home. Each of these trends can change the family dynamic, influencing both parents and children. We will also consider some of the changes to family structure that have become more prevalent in recent decades, including single-parent families, families with same-sex parents, and families in which parents divorce and perhaps remarry, blending two previously separate families. There is now extensive research on what kinds of effects these different family structures have on children and how, in some cases, they seem to vary, depending on the children's age and gender.

Finally, we will consider the prevalence and effects of child abuse. Such cases can range from physical and verbal abuse to incest. These tragedies raise significant concerns about the long-term consequences for children. In addition, they demonstrate potential effects across generations, as abused children become abusive parents themselves, creating a "cycle of abuse." We will also ask about the potential effects of foster care on children. For example, what are the potential tradeoffs associated with placing children in foster care as opposed to keeping them in their own problematic home setting?

In all of these cases, it is important to carefully monitor the kinds of methods that researchers use and the extent to which these methods can support clear conclusions about causal patterns. We will also want to keep in mind the cycles of interactions that can happen in a family and the challenges of disentangling causes from effects. At the broadest level, we will consider families in terms of two complex webs of interactions, one that occurs among family members and another that occurs between the family and the larger culture in which it is situated. Our goal will be to discern some reliable patterns that hold across these two webs of interactions.

Parenting

Parenting can take several forms that serve different functions for the child. One review described seven important components of parenting that guide a child's development (Brooks-Gunn & Markman, 2005). Each of these components forms a continuum with positive and negative forms of parental behaviors at opposite ends. The positive and negative behaviors show dramatic differences in their prevalence and their effects across different socioeconomic and cultural groups, and these patterns are correlated with different outcomes for children.

- *Nurturance* involves showing children warmth and responding to their needs and changing emotions (see Chapter 6). When parents fail to nurture, they may be either disengaged or inappropriately intrusive.
- *Discipline* methods that attempt to explain the reason for a punishment are generally considered more effective than

punishments that are coercive, physical, or insufficiently explained (see Chapter 12).

- *Teaching* a child ideally involves questioning a child carefully to find out where she is coming from cognitively. Parents who are less effective teachers may instead take over the task for the child without considering the child's own mental state, or they may not offer any help.
- The *language* that parents use to engage the child can be adjusted to suit his age and situation, and it can include questions, expansions of the child's utterances, and a rich narrative structure (see Chapter 8). Alternatively, a parent may talk to the child only rarely or may talk "at the child" without encouraging interaction.
- The *materials* that parents provide to foster creative play—like books, toys, and games—enable a child to imagine, explore, and interact more fruitfully with others. Other parents may provide minimal support or prefer materials more useful for "managing" the child, such as sitting him in front of a television for long periods.
- *Monitoring* includes being aware of a child's activities throughout the day, such as where the child is and what she is reading or playing with or watching on television. A low-monitoring parent may be barely aware of a child's activities and may not really have any sense of how a child spends her time.
- Parents *manage* their children's time by arranging play dates or other recurring activities that give a child's life structure and regularity. Parents who fail to adequately manage a child's time might not plan for the days or weeks ahead, leaving the child with no routines and no sense of what is coming next.

Across these seven dimensions of parental behavior, some common aspects distinguish the more positive, balanced ways of interacting with children from the negative ways, which can be either quite rigid or disengaged. In particular, parents tend to vary in the level of warmth and responsiveness they show to their children and in the level of demands or control they place on them. Variations in these broader aspects of parental behavior form the foundation for one of the most influential theories about parenting effects.

Parenting Styles

For several decades, researchers have examined parenting styles and the possible influences of such styles on children. We define **parenting styles** as the ways in which parents engage in behaviors and have attitudes toward their children that create a particular parenting environment or climate. As already noted, the most prominent theory of parenting styles is based on two main ways that parental behaviors vary: the warmth and responsiveness of parents toward their children and the level of parents' demands or control. This theory holds that a parent can be either high or low on each dimension and that a parent's particular combination of warmth and control ends up setting the tone for most interactions between parent and child. Simplifying each of these dimensions into high and low values yields a two-by-two table showing the four most commonly discussed parenting styles (see Table 14.1).

Table 14.1 reflects one of the most active areas of research on parenting (Maccoby & Martin, 1983). The *authoritative*, *permissive*, and *authoritarian* styles were originally proposed by developmental psychologist Diana Baumrind in 1966 (Baumrind, 1966). (The fourth style, *neglectful/uninvolved*, logically results from a low level of both warmth and control, but it was not a major component of Baumrind's original account.) Although threads of these ideas extend back though earlier studies (Grusec, 2011; Hess & Shipman, 1965; Lewin, 1946; Sears et al., 1957), Baumrind initially developed these categories after observing preschool and school-age children in school, in lab settings, and interacting with their parents at home. She also interviewed the parents about how they interacted with their children. The parenting styles that Baumrind proposed appeared quite distinct and were associated with different behaviors and traits in the children.

Over several decades of research and analysis, Baumrind's parenting styles have endured remarkably well (Baumrind, 1991). Given that versions of these types do seem to exist, at least among middle-class North American parents, the obvious question is whether they directly influence aspects of the child. Researchers have frequently addressed this question by looking for correlations between parenting styles and aspects of children's behavior and personalities (see Figure 14.3). Any significant correlations were then assumed to result from the parenting style—the classic fallacy of equating correlation with causation. This is an important concern to keep in mind as we look at each parenting style and the patterns of correlation with developmental outcomes and consider what sorts of causal influences are suggested. Our first examples are limited to middle-class, white, North American children. They mostly pertain to children in early and middle adolescence, as many researchers assume that parenting effects may be the most dramatic after several years of parenting.

	High Control	Low Control
High Warmth	Authoritative	Permissive
Low Warmth	Authoritarian	Neglectful/uninvolved

TABLE 14.1 Parenting styles. Each of the four parenting styles involves a different combination of warmth and control.

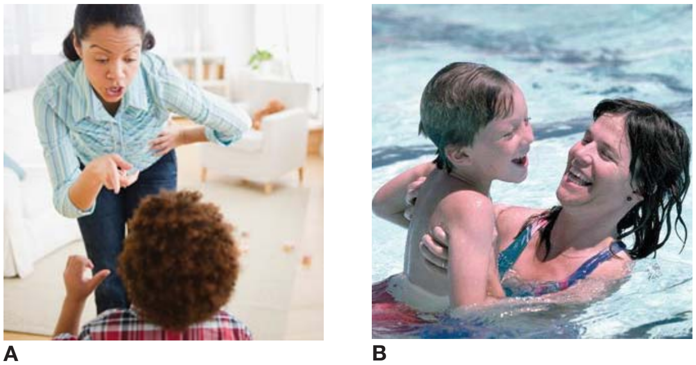

FIGURE 14.3 Links between parenting styles and children's behavior. Parents can differ quite dramatically in their typical patterns of interactions with their children, ranging from authoritarian parents to permissive ones. Such differences in parenting styles have been found to correlate with personality differences in children, suggesting to some that the styles cause the differences. Other factors, however, such as shared genotypes and children's effects on parents, may be equally if not more important in shaping personality types.

Authoritarian parents are low in warmth and high in control and typically order their children around, expecting compliance with no questioning or discussion. Their parenting is often described as harsh, partly because they generally do not try to change a child's behavior through discussion, positive remarks, or rewards. Instead, they tend to use punishment and coercion. In Baumrind's initial description, many authoritarian parents believed they were enforcing behavioral standards based on fundamentalist religious doctrines (Baumrind, 1996). In public places, such as playgrounds or supermarkets, authoritarian parents can sometimes be quite conspicuous—yelling at their children, spanking them, or refusing to put up with any of the children's comments.

Children of authoritarian parents tend to be more dependent and to lack social competence in dealing with peers. They often seem relatively withdrawn and passive and especially compliant to authority figures. In adolescence, they tend to show lower self-esteem and to be more depressed than other children (Baumrind, 1991; Karavasilis et al., 2003). Relative to their peers, boys with authoritarian parents tend to show more hostility, whereas girls tend to set lower goals for achievement. Certainly, this constellation of traits gives the impression that the parents' demanding, overcontrolling approach created passive, withdrawn children who have had little opportunity for independence, self-expression, or initiative.

Quite the opposite of authoritarian parents, **permissive parents** are high in warmth and low in control. They make few demands of their children and rarely attempt to monitor or control their behavior. Instead, they are highly tolerant of their children's behaviors and desires. Their focus as parents is on helping to meet their children's needs and desires rather than on moderating their children's actions. They are often very sensitive to their children's emotions and motivations and try to respond to them without imposing any restrictions. They rarely discipline their children, and when they do, it may be inconsistent: the same behavior is punished on one occasion and tolerated on the next.

Children of permissive parents tend to seem more immature than their peers and to have trouble controlling their impulses or setting limits on themselves. In Baumrind's observations, they are less likely to accept responsibility for their own actions. They also tend to act less independently than other children, which may seem surprising given that they have had so few constraints. As adolescents they are more likely than their peers to exhibit problem behaviors. However, they also show relatively high self-esteem, relatively low rates of depression, and better social skills.

Authoritative parents are high in both warmth and control, but here it is important to take a more nuanced view than the simple two-by-two table suggests. Authoritative parents' "high control" is more balanced and less rigid and overbearing than that of authoritarian parents. Authoritative parents set guidelines for their children's behavior, but they are also flexible and will listen to children's concerns and needs. They favor positive feedback and rewards as opposed to punishment or coercion. Discipline is consistent, and the parent usually explains the reasons for punishment, along with requesting that the child make amends for the transgression. (If an older brother takes a younger sibling's toy, he might be asked to apologize, return the toy, and perhaps loan his brother one of his own toys for a while.) Authoritative parents are warm and sensitive to children's mental states, but they do not simply capitulate to their children's desires. They encourage their children's autonomy while upholding guidelines for appropriate behavior.

Children of authoritative parents seem to fare best among Baumrind's groups. They tend to be relatively independent and self-reliant and have good self-control. They do well in high school relative to the other groups and often take the initiative in various matters. Compared to their peers, boys with authoritative parents tend to be more socially responsible, while girls tend to be more independent. A child with authoritative parents seems to be his or her own person, having internalized standards of self-restraint and achievement.

Like authoritarian parenting, authoritative parenting also involves a form of control over children, but it is important to closely consider what kind of control. Several researchers have stressed that psychological control differs in several ways from behavioral control (Barber, 1996, 2002; Barber et al., 2005; Steinberg, 1990, 2005; Steinberg et al., 1989, 1994). *Psychological control* involves attempting to regulate a child's behavior by manipulating his feelings. These manipulations can include withdrawing affection from the child or inducing guilt or shame. Psychological control can include a parent's intrusions into a child's deeply personal domains, in which she feels she should have autonomy, especially as an adolescent (Steinberg, 2005). Psychological control, which is more typical of authoritarian parents, is often associated with more depressive and anxious symptoms in children (Steinberg, 2005). *Behavioral control*, in contrast, involves attempting to regulate a child's behavior by setting guidelines that follow the norms and values of the family or society—perhaps by requiring certain homework hours, a set bedtime, or appropriate ways to speak to older adults. Compared with psychological control, behavioral control is more common among authoritative parents and is generally associated with fewer negative outcomes in children.

Finally, while Baumrind's initial focus was not on the fourth cell, it is important to mention the *neglectful/uninvolved parents*, who seem to ignore and not care about their children. They do not interact much with their children, which makes their style almost a form of nonparenting. They might be oblivious to the child's hopes, desires, and fears and uninterested in monitoring the child's behaviors. This category is less discussed than the others, but may be more likely among parents who struggle with many problems of their own, making them unable to function well as parents. Imagine, for example, a single mother who is deeply clinically depressed. She has little motivation to do anything more than the bare minimum required to get through the day. Her child is largely irrelevant to her. In other cases, a parent may actually develop feelings of hostility toward a child that consequently contribute to a tendency to be neglectful and uninvolved.

Children of neglectful/uninvolved parents tend to fare badly. One especially clear pattern is their tendency to be especially susceptible to peer pressure and therefore to engage more often in behaviors that do not conform to adult norms (Bednar & Fisher, 2003; Durbin et al., 1993; Shucksmith et al., 1995). Some studies have suggested that girls with neglectful/uninvolved parents are more likely than other girls to become involved in peer groups whose norms are clearly different from those of the dominant adult culture (Brown et al., 1993; Lamborn et al., 1991). Table 14.2 summarizes the features of each parenting style and some of the associated developmental outcomes.

Q: What are Baumrind's three parenting styles, and how are they associated with psychological differences in children? When and how is gender of the child relevant?

Parenting Contexts

Many of these differences among children seem to fit with causal explanations of how parents might influence their children. But accounting for cross-cultural and social class differences inevitably complicates those causal stories because the associations between parenting styles and children's behaviors differ across cultural and socioeconomic groups.

Parenting across Cultures Even when a parenting style appears to be the same across several cultures, it can

	Parents	All Children	Boys	Girls
Authoritarian	Low warmth, high control (overbearing, rigid, psychological control)	Dependent, low social competency, look to authority	Hostile	Set low goals
Permissive	Low warmth, low control	Immature, low impulse control, not inclined to take responsibility or act independently	No obvious gender differences	No obvious gender differences
Authoritative	High warmth, high control (balanced, flexible, behavioral control)	Self-reliant, self-controlled, willing to explore	Responsible	Independent and socially responsible
Neglectful/ uninvolved	Low warmth, low control	Strongly influenced by peers		May show a greater tendency to join peer groups that depart from adult norms

TABLE 14.2 Effects of parenting styles Four different parenting styles have been consistently associated with particular kinds of behaviors and traits in middle-class North American children.

nonetheless mean very different things—and be associated with different outcomes—depending on each culture's social norms. Contrast, for example, Chinese-American children and European-American children. A parenting style with many authoritarian components is associated with much better outcomes among Chinese-American children than among American children of European descent. Part of the explanation for this difference may lie in the different meanings that highly similar parental behaviors can have across cultures. Although Chinese-American parenting practices superficially resemble those of authoritarian parents in North America, many Chinese parents are driven more by a philosophy of training than one of domination and control (Chao, 1994, 2001). That attitude in turn is undoubtedly linked to cultural differences in the extent to which people's abilities are thought to result from training and hard work as opposed to being fixed and intrinsic. (Many Asian cultures regard traits such as intelligence to be much more dependent on training than North American cultures do.) Thus, many East Asian children may interpret authoritarian-looking parenting styles as concerned with training rather than as overbearing or intrusive.

A specific culture may therefore provide a radically different way of understanding an action than the way a child from another background would understand it (Darling & Steinberg, 1993; Hatano & Wertsch, 2001). At the same time, Chinese-American children do seem to sense a tension between the typical levels of parental warmth and control of the broader culture and the warmth and control shown by their parents. They often have internalized the norms of the broader culture and thereby see their own parents as being less warm than normal (Wu & Chao, 2011). In this way, they have a different experience from children in China, where that tension does not exist, while also having a different experience from European-American children. More broadly, children acculturate in different ways and to different extents than their parents, and those differences can be sources of tension in the family (Telzer, 2011).

Parenting across Socioeconomic Groups Parenting styles not only differ across cultures, but they also differ across socioeconomic groups within cultures. Thus, it has been repeatedly found that families of higher socioeconomic status (SES) use authoritative parenting styles more often (and use authoritarian styles less often) than working-class or poor families. The differences can be substantial. In one study, upper- or upper-middle-class parents talked with their children twice as much as those in the most impoverished class. They also used only half as much language forbidding actions and used far less physical coercion. Perhaps most dramatically, the high-SES parents gave their children six times more positive feedback than parents from the most impoverished groups (Hart & Risley, 1995). Similar patterns have been found across many studies and a variety of cultural settings. Economic hardship and other life stressors are strongly associated with a drop in both parental social responsiveness and parents' warmth and empathy toward their children (Huston & Bentley, 2010).

These patterns can also shift as life circumstances change. Thus, mothers who leave welfare support and escape poverty are less likely to use authoritarian child-rearing patterns than those who leave welfare but remain poor (Smith et al., 2001). Parenting styles can even vary from day to day, depending on the parent's stress level. In one study, air traffic controllers who were monitored at work and at home were less involved, less effective, and more negative as parents on days when their work was highly stressful (Repetti, 1994). The same pattern holds for parents who have stressful days in other work settings (Crouter & Bumpus, 2001; Repetti & Wood, 1997; Repetti et al., 2009).

One interpretation of the relationship between hardship and certain forms of parenting suggests that more controlling styles may be appropriate in times of risk and threat (Fischer et al., 2010; Harrison et al., 1990). If a child's safety is jeopardized by not obeying his parents, then the parents will need to be as firm as possible, especially in a chaotic and distracting environment. Poverty can bring enormous stresses for parents, as well as increased risks to children's well-being, whether through higher crime rates, more hazardous home environments, or more competition for scarce resources. One study found that simply reminding parents of terrorist incidents resulted in more authoritarian parenting behavior toward their children (Fischer et al., 2010). In stressful, risky environments, it is possible that an authoritarian parenting style would be adaptive. Along similar lines, most parents become more authoritarian in moments of high stress and danger. You probably recall a time when, spurred by an immediate threat, a caregiver suddenly shifted from warm and interactive to urgent, dictatorial, and controlling. Indeed, the situational specificity of parenting styles is an important topic that has received relatively little research attention.

Although authoritarian styles might sometimes be more adaptive and appropriate for groups at risk than for those who are well-off, this is not always true. Sometimes the differences do not benefit the child and instead merely reflect the demands of a difficult life. Imagine, for a moment, that you are a single parent with three young children. While you work long hours in an exhausting, menial job, you have to leave your children in substandard day care because there is no better alternative that you can afford. You live in a crowded, rundown apartment building with only intermittent heat and electricity. You return from work with the children in tow and have to cook dinner, change their diapers (which were neglected at day care), and help the oldest child with his homework. It is hardly surprising that this parent would lack the energy to have rich, interactive conversations with the children. It would be easier, at least at first, to give clear orders and back them up with threats of punishment. In the short term, authoritarian parenting styles can often produce quick behavioral changes more easily. In the long term, however, those styles may become less effective, resulting in the range of negative behaviors more commonly seen among children of authoritarian parents.

The Ecological Systems Approach The influence of context has been described in a broader sense as the **ecological systems approach** to families, which emphasizes that contextual factors, including culture and social class, among others, are crucial to understanding the child's development within a family (Bronfenbrenner, 1977, 1979, 1986). This approach, which was devised by developmental psychologist Urie Bronfenbrenner, considers the child's environments at several scales, ranging from the family itself, to the school, to the larger culture. In addition, other environments, such as the parents' workplaces, may indirectly affect the child by limiting the parents' time for interacting with the child or through the child's experiences in day care. According to ecological systems accounts, attempts to characterize how families are important to a child's development must consider the child's role in each of these "social ecosystems" and how that role interacts with other participants in the systems. Ecological approaches attempt to shed light on the influences of a child's many social contexts by drawing parallels to the ways that organisms interact in biological systems. We will return to Bronfenbrenner's ecological systems approach in Chapter 15 as part of our consideration of children's roles in social systems outside the family. These other systems include peer relationships, social groups, the media, and the larger culture in which a child develops.

Q: How do different parenting contexts like culture and SES affect the associations between parenting styles and children's psychological outcomes?

Interventions to Improve Parenting

Over the past few decades, researchers in North America and elsewhere have offered courses in parenting skills, specifically targeting groups that are more likely to show authoritarian or neglecting/uninvolved parenting styles (Cowan et al., 1997). These interventions are based on the belief that even in stress-ridden families, the authoritarian style is still not best for either the children or the parents. A number of these interventions have shown positive effects for both parents and children. The most compelling studies randomly assigned parents to either a group that received instruction on parenting skills or a control group that was involved in an activity unrelated to parenting (Cowan & Cowan, 2002). This experimental approach enabled the researchers to disentangle mere correlations from causal influences. In several such studies, the children of parents who were coached to be less coercive and more interactive showed corresponding improvements in behavior (Spoth et al., 2001). Training generally focused on creating opportunities for positive family interactions, establishing appropriate expectations about children and appropriate monitoring and discipline, teaching parents how to coach their children to resist peers when needed, reducing and managing instances of family conflict, and emphasizing the value of displaying positive emotions.

The issue of parenting interventions becomes especially important in the context of large-scale programs such as Head Start. As described in Chapter 11, Head Start targets millions of lower-income children throughout the United States in an effort to increase school readiness. A related program, Early Head Start, focuses on children between birth and 3 years. One facet of both programs is to teach parenting skills to lower-income disadvantaged parents. It was assumed that such interventions might also promote school readiness by fostering more learning-rich interactions between young children and those around them. There have been many analyses of the outcomes of such programs, and a consensus seems to be emerging that parenting skills can be successfully taught in such large-scale programs (Brooks-Gunn & Markman, 2005; Zhai et al., 2011); and, in at least some cases, interventions in random assignment studies have been linked to higher levels of school readiness (Sheridan et al., 2011). Thus, parents can, with guidance, become more attentive, less coercive, and more interactive with their children. Interestingly, the effectiveness of these interventions differs, depending in part on the parents' race. These interventions tend to have a large effect with African-American parents, but they often show no effect with European-American parents (Sheridan et al., 2011). The reasons for these group differences are not yet clear.

Will the parents who undergo training maintain a warmer, more interactive parenting style in the face of continuing life stresses? And do the effects on children's behavior with their parents have a positive influence on relationships with other adults or with peers? These questions are essential to understanding whether the considerable public funds expended on programs to improve parenting skills are well spent. It may be that these interventions, focused on directly reaching the affected individuals, are the most powerful approach, especially as they become more carefully tailored to specific groups of parents and children at risk (Hutchings & Lane, 2005; Shonkoff & Meisels, 2000). Unfortunately, such approaches can also be the most labor and skill intensive.

More broadly, most studies have found modest, but enduring positive effects of Head Start and Early Head Start interventions, especially with respect to measures such as grade repetition and behavioral problems in school (Deming, 2009; Joo, 2010; Ludgwig & Phillips, 2008; Sheridan et al., 2011; Zhai et al., 2011). However, test scores and other academic measures tend to show diminishing effects with increasing age, and some scholars have concluded that long-term benefits in academic achievement are rare (Gibbs et al., 2011). If interventions involving parental training are one of the key routes to having a positive influence, it may make sense that long-term benefits of such programs are more associated with broad behavioral measures than with more narrowly defined academic outcomes.

Parent Effects in Relation to Other Influences

It is tempting to see parenting as the primary influence on a child's personality, but some scholars have argued that the correlations we have examined between parenting styles and children's behaviors have been mistakenly interpreted. Rather than studying how parents affect their children's behaviors and traits, they have largely focused on child effects—the ways that children influence their parents' behavior—as well as on genetic factors that could influence parents and children similarly (Bell & Harper, 1977; Harris, 1998; Rowe, 1994). While the correlations between parenting styles and developmental outcomes are statistically significant, they are often relatively small, making it easier to argue for these alternative accounts. Nonetheless, the evidence for child effects and common genetic influences does not reduce or exclude parent effects. In many cases, these factors interact with patterns of parenting.

Child Effects Whenever the child's traits or behavior causes the parents to act in a certain way in response, **child effects** are at work (see Figure 14.4). Consider, for example, an inhibited, shy child whose parent tends to encourage him to be cautious. Does this correlation suggest that the parent is fostering the child's timidity, or is the child's timidity eliciting more protective behavior from the parent? First impressions might suggest a dominant role for parents, but the child can have major effects as well. In one study of 125 U.S. 3-year-olds and 100 Korean 3-year-olds, researchers carefully coded videotapes of the more inhibited children, recording whether parents encouraged the children to approach or withdraw from novel threatening stimuli and how often they discouraged the children's tendencies to withdraw (Belsky et al., 2000). In this case, the children were largely driving their parents' behaviors, especially that of their mothers. In particular, the more inhibited children elicited a wider range of parental responses: the more a child withdrew from interactions, the more the parents tended to

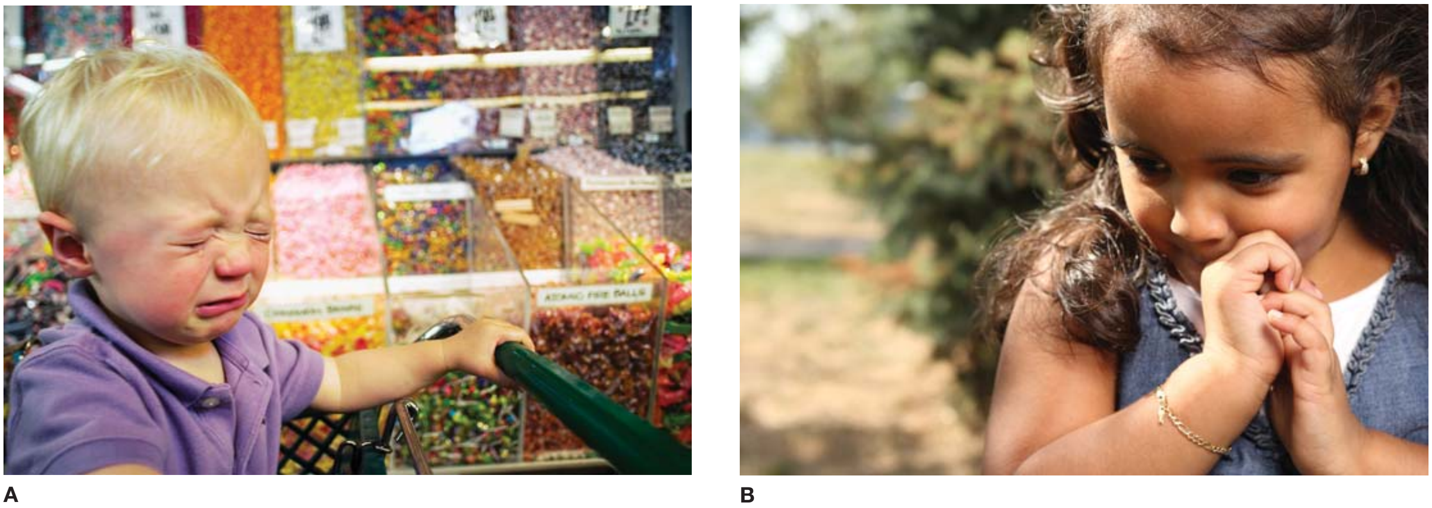

FIGURE 14.4 Child effects. Although researchers traditionally tended to emphasize the effects of parental behavior on children, the children themselves may have a powerful influence on their parents. For example, **(A)** a child who repeatedly throws tantrums may elicit very different behaviors in his parents than **(B)** a child who is excessively shy.

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

Epigenetics and Families

As described in Chapter 2, epigenetic regulation is one way that environmental influences can affect the activity of genes. This kind of gene regulation occurs when the chemicals surrounding a particular cell type affect which of the cells' genes are active or inactive, such that when the cells divide, the genes of all the cells that they create can have the same pattern of active and inactive genes. As epigenetics becomes an increasingly important aspect of the study of development, it is beginning to illuminate some of the surprisingly strong ways that parents, children, and siblings influence each other.

For some time, researchers have been able to demonstrate powerful epigenetic effects in animals, most notably in rats and mice. For example, when a rat pup is frequently licked by its mother, chemical changes to a certain gene related to hippocampal function cause other genes to trigger the production of higher levels of neurotransmitters, such as serotonin, in the young rat (see Figure 14.5). That increase in neurotransmitter levels in turn seems to bias the rat pup to be less fearful and less reactive in stressful environments. Rat pups whose mothers lick them less often do not undergo these genetic changes, which results in lower levels of neurotransmitter production and more fearful and reactive behavior (Caldji et al., 1998; Meaney, 2001; Meaney & Szyf, 2005; Weaver et al., 2004). Thus, early maternal behavior can affect the activation or deactivation of a particular set of genes, resulting in a long-term effect on the offspring's physiological and psychological responses to stresses. This kind of effect initially was thought to be irreversible after gene expression was "fixed" early in life. However, follow-up studies have shown that these maternal effects on offspring's genetic activity can be reversed through drug treatments in adult rats (Champagne et al., 2008; Weaver et al., 2005, 2006).

FIGURE 14.5 Epigenetics and parental care. When rat mothers lick their offspring more, that increased care can turn on gene pathways that produce more neurotransmitters involved in reducing anxiety. Thus, a rat mother who is not stressed and who is able to devote more extensive care to her offspring can cause the genes correlated with lower anxiety to switch on in her offspring.

It is, of course, a great leap from mother rats licking their pups to the possibility of epigenetic effects of parenting in humans. But researchers in both animal systems and human development have drawn parallels, and work with nonhuman primates has strengthened those parallels. In some studies, an important manipulation has been to compare peer-raised and mother-raised monkeys (Suomi, 1997, 2005). As mentioned in Chapter 6,

either encourage approach and discourage withdrawal—or, on other occasions, encourage the inhibition. The child's shyness affected the parents by making his interaction with (or withdrawal from) peers a more central issue in parent-child interactions (Rubin et al., 1998).

The clearest way to study child effects is to set up an interaction that can be repeated by many parent-child pairs. Researchers can experimentally "manipulate" the child's behavior by randomly assigning children to behave in particular ways and then compare the effects of the child's behavior on parents' responses. In one study, children were randomly assigned to be either compliant and cooperative or resistant and noncooperative while performing a task with an adult stranger (Bugental et al., 1980). In general, the same adult would much more likely slant toward an authoritarian style with a less cooperative child. A more naturalistic, longitudinal study of children with conduct disorders found similar patterns: when difficult children misbehave, that bout of misbehavior triggers more authoritarian behavior in parents, who then exercise more control and use more negative coercions (Dodge, 2002). Other studies suggest that negative temperaments in children cause negative reactions in their parents, although these studies are not experimental and depend on complex statistical analyses to infer child temperament effects on parenting as opposed to effects in the opposite direction (Ganiban et al., 2011; South et al., 2008). At least one study has shown that difficult temperament-related behavior in rhesus macaques raised in a peer group without adult macaques do develop attachment bonds with their peers, but they are also more fearful than those raised by adults. More importantly for the epigenetic hypothesis, the peer-raised macaques show neurological differences. They have less developed neural networks using the neurotransmitter serotonin, especially in brain areas related to inhibitory control and emotions (Ichise et al., 2006). These similar patterns across monkeys and rats have led some researchers to suggest that a similar epigenetic effect may hold in humans as well (Branchi, 2009).

In humans, the activities of genes involved in producing the neurotransmitters oxytocin (discussed earlier in Chapter 6), serotonin, and dopamine are related to feelings of interpersonal trust and intimacy and behaviors associated with sensitive parenting (Bakermans-Kranenburg et al., 2003; van IJzendoorn et al., 2011). When parents whose genes trigger lower levels of oxytocin, serotonin, or dopamine are exposed to stress or daily hassles, they are more likely to show less sensitive parenting. That is, parents with certain genotypes seem to be at greater risk than other parents to resort to insensitive parenting when they are put under stress.

Building on these findings as well as the epigenetic studies in nonhuman animals, researchers are now asking whether experience-induced regulation of genetic activity could also influence such behaviors as parenting. Based on the animal work showing how stressful environments can alter gene pathways, and based on the work showing how neurotransmitter levels in humans can influence behaviors related to parenting (Domes et al., 2007; Feldman et al., 2007; Kosfeld et al., 2005), it now seems plausible that stressful social situations experienced early in life could have far-reaching epigenetic effects. Stressful experiences during childhood could downregulate gene pathways, altering neurotransmitter levels and potentially making these individuals less sensitive as parents (Champagne & Curley, 2008; Ogren & Lombroso, 2008). Some of these chemical changes involved in gene regulation could last a lifetime and even be passed on to offspring (Ogren & Lombroso, 2008), although, as noted earlier, such effects have been reversed in animal studies. It is not yet clear just how common such cases of transgenerational epigenetic inheritance are for psychological traits in humans (Grossniklaus et al., 2013).

It is too early to develop full-fledged epigenetic explanations for the variations in interactions between parents and children, but there is a strong possibility that epigenetic influences are significant (Szyf et al., 2008; van IJzendoorn et al., 2011). More generally, the epigenetic perspective goes beyond analyses of genetic effects to show how, even at a molecular level, genotypes and environments continuously interact. Consider, for example, how one study has shown a link between human parenting and epigenetic changes in children (Essex et al., 2013). Parents were interviewed about the levels of stress in their own lives when their adolescent children were infants or young children. Reports of high levels of parental stress, especially in mothers, were then related to increased levels of methylation of DNA in cells scraped from the inside of the cheeks of their adolescent children. (Methylation is thought to be the primary way in which specific genes are turned off and, less commonly, turned on.) Future research will have to demonstrate comparable methylation effects on neurons and then link those changes to neurotransmitter levels and behavior. Such pathways of influence seem increasingly likely in humans, especially given their presence in other species.

children may have a causal influence on higher levels of physical mistreatment and neglect by the parents (Schulz-Heik et al., 2009).

Other studies have shown that parents' perceptions play as important a role in child effects as children's behavior does. When researchers experimentally manipulate parents' perceptions of whether or not their children's misbehavior was intentional, those who perceive their children as acting out on purpose respond with harsher, more intense discipline (Slep & O'Leary, 1998). Parents' perceptions can also interact with child effects. For example, parents who perceive themselves as having little control over children tend to react more strongly and harshly when children are uncooperative (Bugental et al., 1993, 1999, 2000).

Q: How is the study of child effects relevant to the study of parenting?

Genetic Effects We have considered how parents influence children via parenting styles and how children influence parents via child effects. But in some cases, correlations between parents' and children's behavior may be best explained by a third factor—the genes that parents and children share. Thanks to substantial advances in behavioral genetics, researchers are beginning to disentangle some of the interactions between genes and behaviors that pertain to parenting.

Although some behavioral geneticists have focused on understanding genetic influences on either the parent's behavior or the child's behavior, another approach offers an account distinct from parental influences and child behavior. Instead of a one-way influence of the child on the parent (or vice versa), the parent and a child might share a genetic disposition toward a particular trait, such as shyness or irritability. That shared disposition could then cause a strong correlation between a particular style of parenting and a particular kind of behavior from the child. Likewise, if withdrawn parents tend to have withdrawn children, it may not be the parents' behavior or the children's behavior that causes the correlation, but the third factor of their shared genotype. It is important to remember, however, that even with shared genotypes, phenotypic expressions of those genotypes may be quite different in young children and adults. Thus, a toddler who has a genotype that makes him irritable and therefore prone to crying fits and physical tantrums when frustrated is not likely to have a parent who behaves in the same way, even if the genotype for their irritability is shared. That parent may be volatile and reactive but is unlikely to plop down on the grocery store floor, burst into tears, and have a physical tantrum.

Behavioral genetic studies cover more than shared genotype effects and accounts of how certain genotypes are related to child and parent effects. In animal studies, researchers are also making headway in understanding the epigenetic mechanisms through which some parental behaviors can affect genetic activity in offspring (see the New Directions in Developmental Research box). As more sophisticated techniques emerge for studying the entire human genome and looking at complex interactions between sets of genes, a much more diverse set of causal pathways between behaviors and genes is likely to be part of any discussion of parenting.

Q: How can a behavioral genetic approach explain correlations between parents' and children's behavior without primarily relying on either parent effects or child effects?

The Interactionist Approach to Family Dynamics

Genetic effects and child effects do not necessarily diminish the effects of parenting on children. Instead, taken together, the three types of effects suggest a much more complex, interactional way of understanding family dynamics (Dodge & Pettit, 2003; LaFreniere & MacDonald, 2013; Maccoby, 2000; Parke, 2004). A particular kind of parenting may benefit some kinds of children much more than others, and for some it may even be detrimental. Similarly, some parenting effects may depend on aspects of the child that change over the course of development, initially exerting little immediate sway, then strongly influencing the child for a period of time before waning.

Consider one example of how an interaction pattern between parent and child might change with development because of both parent and child effects. A parent who is prone to ordering children about might do so to a greater extent with smaller and less vocal children who cannot respond adequately to this behavior. Thus, authoritarian parenting might wax and wane as a child develops. This case illustrates how more subtle differences in temperament and personality of children and parents can create quite intricate patterns of interaction. There are now "biopsychosocial" approaches that see certain combinations of biological disposition, psychological tendencies, and sociocultural contexts as likely to either increase or decrease children's risk of some adverse outcomes (such as becoming aggressive toward others) early in life. These approaches also seek to account for ways that experiences with parents, peers, and the broader social world either increase or reduce that risk (Dodge & Pettit, 2003). Figure 14.6 shows one model of the ways these interactions could contribute to conduct disorder, which is a behavior pattern in children and adolescents that involves repeated incidents of actions that infringe on the rights of others. It is often called "antisocial behavior."

The interactionist approach is valuable for its broad yet nuanced view of the many influences affecting both parents and children, but its critics have cited one serious

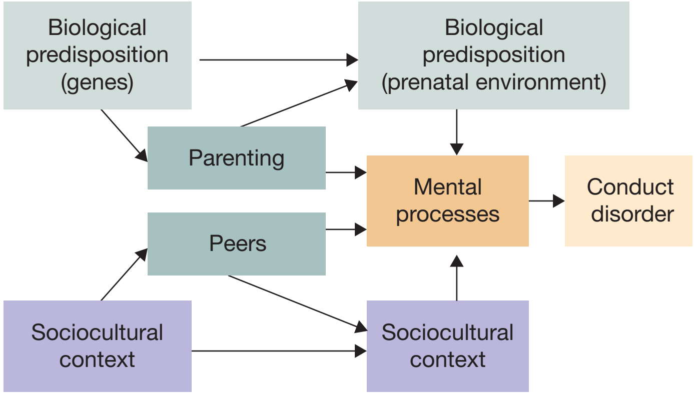

FIGURE 14.6 Interactionist models. As this sample interactionist model shows, interactionist views of parenting incorporate many kinds of effects, including biological (both genetic and toxic prenatal environment), sociocultural, and peer influences, that may moderate or exaggerate parents' effects on children (here operationalized as children with conduct disorders). These models, however, can be frustrating to test because it is often unclear what kinds of outcomes they would predict. Adapted from Dodge & Petit (2003).

drawback: it is almost always possible to explain a set of observations in terms of the many complex interactions that likely influenced the outcome. It is much harder to use an interactionist model to predict such effects in advance and then test those predictions as a way of evaluating the model. Moreover, these models are especially tough to test because they depend on intricate webs of interactions in which it is difficult to disentangle causal relationships from mere correlations. The interactionist model is clearly a more comprehensive approach to studying parenting and effects on children. At the same time, it highlights the challenges for future researchers in developing more complex and sophisticated methods of accounting for the influences at work in parent-child dynamics.

Despite the clear merits of the interactionist view, there is also a need for further research documenting which parental behaviors contribute the most to these systems of interactions. For example, a great deal of traditional research has asked how parenting practices might affect a child's personality traits, but personality is invariably the result of a host of interactions in which parenting is just one component. Other aspects of the child, however, may relate more indirectly to parents' behavior. By choosing where a family lives and what elementary school a child will attend, parents greatly influence the pool of potential friends and teachers that a child will have. Parents might affect a child's hobbies by simply exposing her to certain activities. Similarly, children's knowledge of etiquette or specific cultural practices depends significantly on how their parents live.

A final point concerns the implications of the interactionist model for parenting. If a wide variety of interacting influences are at work in all parent-child dynamics, the most effective parents would need to be sensitive to the child's nature and be able to adjust parenting strategies accordingly. Not all parents tailor their approach to their children as individuals, instead tending toward one style for all their children. By acknowledging a wide variety of influences on family members, the interactionist approach suggests that parents and children who are able to respond to one another's individual natures will have the most positive relationship (Grusec et al., 2000; Kochanska, 1997b, 1998). Indeed, the long-term pattern of interactions between a particular child and parent may be far more important for understanding parenting effects than a number of brief, specific parent-child interactions, since the same pattern of parental behavior may be interpreted very differently at different times, depending on the long-term context of the relationship.

Q: What are the strengths and weakness of the interactionist approach to studying parenting?

Gender Socialization in the Family: A Web of Interacting Influences

Boys and girls tend to behave differently on many dimensions, ranging from favorite activities to patterns of social interactions. These differences raise questions about the relative contributions of parents, children, social/cultural context, peers, and genes in influencing those behaviors. We will see that the development of gender-typical behaviors vividly illustrates the interactionist perspective in which all of these factors influence each other rather than simply making independent contributions. The massive amount of research on parenting and children's gender supports the common sense intuition that parents treat children of the two sexes differently (Leaper, 2002, 2011; Lundberg, 2005; Lytton & Romney, 1991; Raley & Bianchi, 2006). Parents tend to offer children sex-stereotyped toys, such as giving trucks to boys and dolls to girls; and they tend to interact with their children in ways that reflect their notions of the differences in girls' and boys' behavior, inviting boys to be involved in more physical activities and girls in more social and conversational ones. Table 14.3 summarizes some of these differences. It is important to keep in mind, however, that while these differences are reliable, they are usually surprisingly modest, especially with children younger than 6 years of age (Maccoby, 2003; Maccoby & Jacklin, 1974; Russell & Saebel, 1997).

One way of explaining gender socialization focuses on the ways that parents' gender schemas affect children. **Gender schemas** are cognitive systems for interpreting gender-related activities and roles (Bem, 1981). They are shaped in parents by the norms and stereotypes that exist for each gender in a parent's culture. For example, when parents were asked to teach their grade school children how to perform three tasks involving physical science, computer programming, and hypothetical interpersonal dilemmas, the language the parents used varied, depending on the sex of the child, the content the parent was teaching, and the parent's gender schema (Tenenbaum & Leaper, 2003). Fathers used more cognitively demanding speech when asking questions about science problems with their sons than they did for similar problems for their daughters. Similarly, when children ask about why some natural phenomenon occurs or how a device works, parents tend to offer more complex and cognitively deeper explanations to boys than to girls (Crowley et al., 2001; Tennenbaum & Leaper, 2003; Tennenbaum et al., 2005). One study found that parents also are three times as likely to offer scientific explanations to boys as to girls in everyday conversations, even though both boys and girls ask for such explanations to roughly equal degrees (Crowley et al., 2001). Parents can also influence their children's choices about courses of study in middle school, selecting more math and science courses for their sons than for their daughters (Tenenbaum, 2009).

	Conversational Interactions	Manner of Play	Reactions to Emotions
Boys	Both parents talk to boys somewhat less and focus more on nonpersonal or intrapersonal topics.	Both parents play more roughly with boys and offer them toy vehicles and sports equipment to play with.	Fathers react negatively to crying, fearfulness, or other expressions that could signify weakness in boys.
Girls	Mothers talk to girls more overall and specifically about emotions.	Both parents play more gently with girls and offer them dolls and props for playing house.	Both parents are more tolerant of displays of distress and fear-related emotions in girls.

TABLE 14.3 Some differences in how parents socialize boys and girls. The effects of parental socialization vary as a function of the gender of the parent and that of the child; usually, same-gender pairs have the strongest influence. Nonetheless, these differences are often more modest than expected, especially when children are younger than 6 years of age. From Maccoby (2003).

Gender biases in adults also seem to be more tolerated by children than other forms of biases. Thus, in one study in Denmark, when children were asked to make judgments about exclusion from activities based on gender as opposed to ethnicity, they thought that exclusion based on ethnicity was less acceptable and more morally inappropriate (Moller & Tenenbaum, 2011). This pattern follows earlier studies in the United States showing a greater willingness to tolerate exclusion based on gender than on ethnicity (Killen, 2007). Thus, parents may get less negative feedback or resistance when they show gender bias as opposed to other forms of group biases.

In general, even though parents interact differently with their sons and their daughters across a wide spectrum of behaviors and situations (see Figure 14.7), like so many other aspects of socialization, it is difficult to show how these gender-related differences in parenting actually affect the children. Even when there are strong associations between parents' behaviors and gender-related differences in children, it is difficult to prove that parenting actually *caused* the differences in children. To understand why it is so hard to show a causal effect, we will now consider some models of parenting influence.

FIGURE 14.7 Gender and parenting. There are modest but consistent differences in how parents of each sex interact with children of each sex. The impact of these differences on the children is less clear.

Even though studies of parent effects have tended to dominate the research on parenting and gender, children's behaviors can also strongly influence their parents. For example, girls and boys often have strong toy preferences well before 2 years of age, before they experience gender-stereotyped toys or related interactions with their parents (Maccoby, 2003). That is, they bring to their early interactions certain behavioral patterns that may lead the parent to conclude that the child prefers one kind of toy to another and then offer what the child seems to want. This pattern sometimes surprises parents who avoid gender-stereotyped toys so as not to impose gender roles on their children. More formally, researchers have long known that even when we factor out differences in parents' behaviors in terms of the types of toys they provide or offer to their sons and daughters, the children still show gender-based differences in toy preferences (Calders et al., 1989). If parental socialization cannot fully account for young children's early gendered preferences, what other explanations are possible?

One alternative approach suggests that children have biologically determined biases that influence their preferences in ways that are initially independent of socialization, biases that may have counterparts in other primates. It may seem implausible that a child's biological sex might somehow directly bias him or her toward gender-stereotyped toys, but several studies have supported that possibility. For example, the extent to which a female fetus is exposed to testosterone seems to relate to the likelihood that she will later show a tendency to like toys that boys normally prefer. This association has been shown in rare cases where a female fetus has the inherited adrenal gland disorder known as congenital adrenal hyperplasia (CAH). CAH results in exposure to higher than normal levels of masculinizing hormones, such as testosterone, in utero. Girls born with CAH show increased preferences for playing with gender-atypical toys (Berenbaum & Beltz, 2011; Cohen-Bendahan et al., 2005;

Hines, 2013; Pasterski et al., 2005). Even when two girls are born to the same family, the girl born with CAH shows more of a preference for gender-atypical toys than her sister born without CAH (Pasterski et al., 2005). Girls with CAH also tend to show a higher preference as teenagers for future occupations involving "things" (such as auto mechanic or jet pilot) than those involving "people" (such as social worker or teacher; Beltz et al., 2011).

Because girls with CAH often have more masculine genitalia, it is possible that their parents notice these differences and behave differently toward their two daughters, influencing their toy preferences (Cohen-Bendahan et al., 2005: Jordan-Young, 2011). Additional indirect effects could occur through the intensive medical and psychiatric attention that girls with CAH receive and expectations by parents and others that their daughters will be "masculine" (Jordan-Young, 2011). Such indirect effects, however, are not likely to provide a full explanation for the different behaviors in girls who have higher prenatal levels of masculinizing hormones. In fact, when mothers of girls with CAH are studied, they do not treat their daughters in ways that favor masculine behaviors and, if anything, show more of a bias toward feminine behaviors (Hines, 2010).

Some researchers have examined testosterone levels in the mother's blood during pregnancy and then analyzed their children's behaviors, including toy preferences (Auyeung et al., 2009; Hines et al., 2002; see Figure 14.8). They found that the higher the testosterone levels, the greater the children's tendency to play with stereotypically male toys. Thus, there was a "dose-dependent" relationship between levels of testosterone and the extent to which male activities were preferred. The mothers in these studies were unaware of their own testosterone levels, making parental attitude and behavior effects less plausible in this case. In addition, some studies show that "antiandrogen" compounds that reduce prenatal testosterone levels in boys are associated with decreased levels of masculine play (Swann et al., 2010). At the same time, it is important to note that, in statistical terms, variations in testosterone levels in these studies could account for only part of the variation in toy preferences, leaving room for parental influences as well (Jordan-Young, 2011).

The effects of prenatal testosterone could still be interacting with differences in parenting if parents notice subtle differences in body shape or activity level in girls who have been exposed to more testosterone and then treat them differently. But this account cannot explain the striking findings of toy preferences in other primate species that show no parental socialization related to toy preferences. Studies have repeatedly found that young male monkeys prefer playing with trucks instead of dolls or plush animals, and the females sometimes show the opposite preferences (Hassett et al., 2008; Hines & Alexander, 2008; Williams & Pleil, 2008; see Figure 14.9). It is not yet known which features of the toys drive these preferences, as monkeys clearly have no evolved tendencies to interact with any of these objects. Future studies that carefully and systematically vary the perceptual features of different categories of toys will help researchers understand the real nature of the effect.

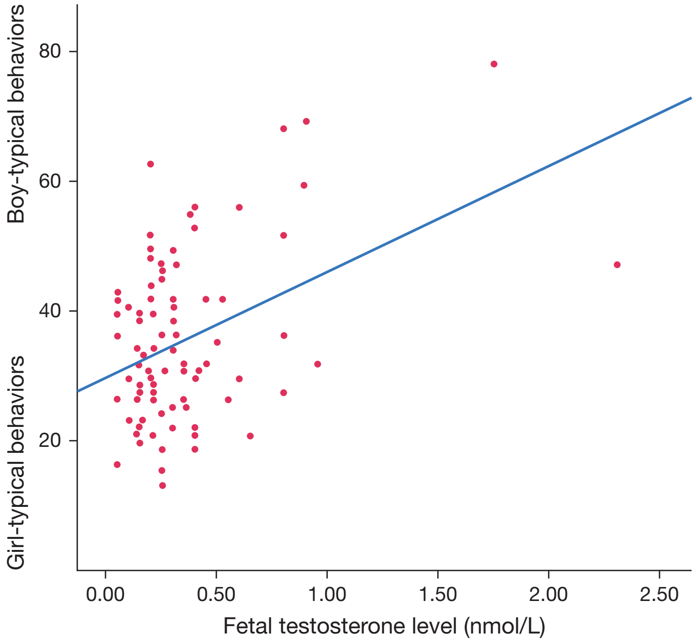

FIGURE 14.8 Prenatal testosterone levels and sex-stereotyped behaviors. Higher levels of prenatal testosterone in girls are associated with greater frequencies of childhood behaviors favored by boys. Adapted from Auyeung et al. (2009).

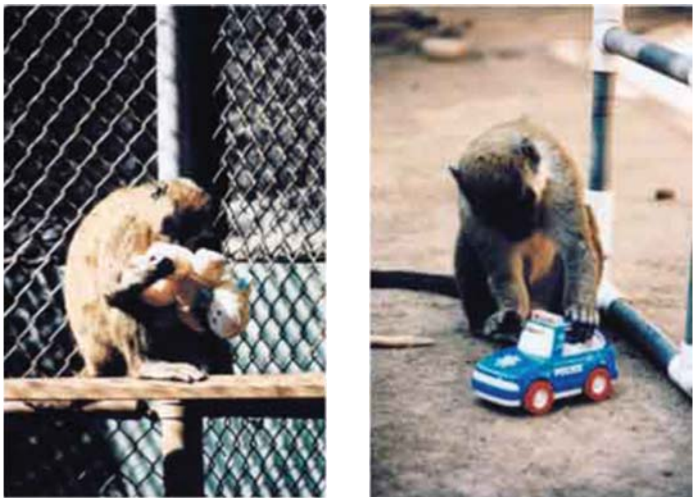

FIGURE 14.9 Toy preferences and gender in vervet monkeys. For reasons that still need to be understood, even vervet monkeys, which have no reason to play with toy trucks or dolls, show gender-based toy choices.

Parental socialization practices can certainly influence toy preferences in boys and girls. Yet, it now seems clear that parents' behaviors are likely to interact with aspects of toy preferences that are present before the occurrence of socialization. In some cases, these presocialization toy preferences can even compete with parental biases. Most of the time, however, parents' gender socialization behaviors and children's early biases probably reinforce each other.

If we take a wider view of familial influences on gender, siblings, too, seem to influence one another's gender role qualities. One study examined families over a 3-year period to determine how siblings' and parents' gender role qualities interacted. To learn whether children influenced the extent to which their siblings adopted gender-stereotyped views and roles, the researchers analyzed the effects of siblings on leisure activities, toy preferences, and ways of approaching social situations (McHale et al., 2001). They found that older siblings' gender role qualities predicted similar qualities in younger siblings 2 years later, even when parents' and younger siblings' initial roles were controlled for statistically. Moreover, the older siblings influenced younger siblings' gender role qualities more than parents did, and their influence was significant in both same-sex and mixed-sex sibling pairs. The older siblings, in contrast, were most influenced by their parents. Thus, parents seem to influence gender roles most strongly in their firstborn children, who then propagate those roles with younger siblings. This may also interact with the finding, noted earlier, that children are more tolerant of gender biases shown by parents and peers than they are of other sorts of biases, such as those involving ethnicity (Killen, 2007; Moller & Tenebaum, 2011). By acquiescing to, or even endorsing, such biases, siblings and peers may reinforce parental behaviors.

Q: Describe at least three different interacting influences that contribute to children's gender socialization.

Siblings and Family Dynamics

We have all heard people explain the behavior of another on the basis of that person's place in the family. Firstborn children, at least early on, frequently have the undivided attention of both parents, whereas later-borns always have to compete for parental resources. In other respects, though, later-born children may have the advantage. They benefit from more experienced parenting, they tend to experience parental tensions less intensely, and they can learn much from their older siblings.

In examining sibling effects, the critical question is whether these kinds of differences in family structure actually influence development. Like the debates about parenting effects, there has been considerable contention, in recent years, as to whether sibling effects are real and substantial (Harris, 2000). The true debate, however, seems to have more to do with the degree of sibling effects than with their existence. When considered in detail, family structure seems to have a modest but broad, multifaceted influence on children.

Birth Order Effects

Of the many factors proposed to be influenced by birth order, the most heavily studied has been intelligence. In 1975, a provocative paper was published showing what seemed to be a correlation between intelligence, as measured by intelligence tests, and birth order. The data indicated that firstborns had the highest intelligence and that intelligence consistently dropped the later a child's position was in the birth order (Zajonc, 1976; Zajonc & Markus, 1975; see Figure 14.10). The documented drop in scores is very modest, sometimes as little as 1 percent of the score of the next oldest sibling, and large population samples are usually needed to find a significant, reliable effect (Kristensen & Bjerkedal, 2007).

This pattern immediately raises the question of whether the birth order effect actually *causes* the difference in scores. One objection is that larger families tend to be more common in lower socioeconomic classes, who also, for a variety of other reasons, tend to score lower on intelligence tests. But when socioeconomic status is held constant, the birth order effect on intelligence remains significant in some populations. More subtle statistical issues have kept debates over the magnitude of the effect alive (Armor, 2001; Rodgers et al., 2000; Wichman et al., 2007; Zajonc, 2001). But despite these disagreements, the current consensus still favors an effect (Black et al., 2011; de Haan, 2010). Moreover, another analysis has suggested that firstborns also tend to complete more years of schooling (Black et al., 2005).

Two potential causes for the birth order effect on intelligence have been frequently discussed. The first, **resource theory**, holds that the more children in the family, the less attention parents can devote to each child. The second explanation, **confluence theory**, argues that as families get larger, their average overall intellectual climate drops (Zajonc & Markus, 1975). Thus, the firstborn child is more likely to be exposed to the parents' more adult-centered discourse, while a fourth-born will more likely be exposed to conversations about toilet training and various cartoon characters.

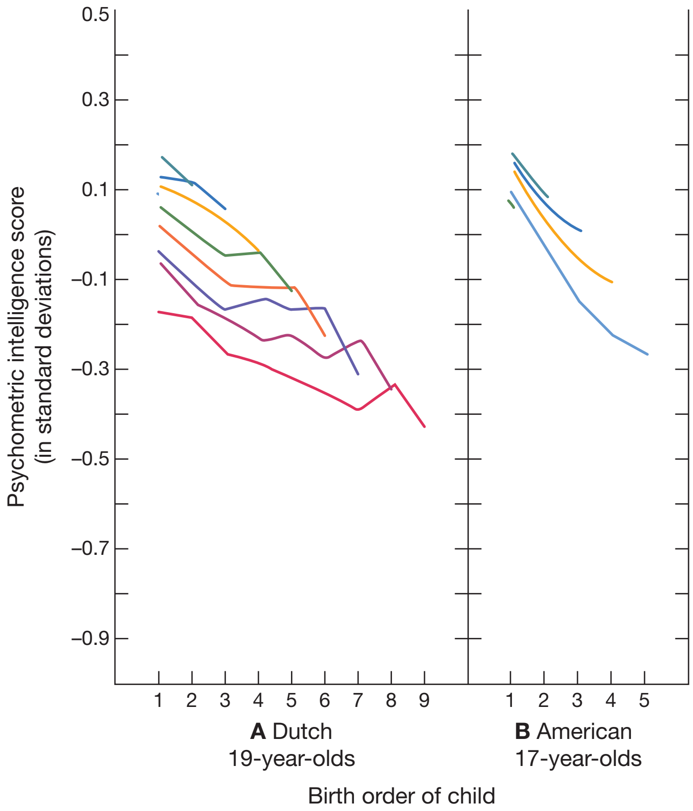

FIGURE 14.10 Birth order and intelligence. These graphs are from very large samples of children in the Netherlands and the United States. They show consistently modest relations between birth order and intelligence. Each curve represents the data for families of the size indicated by the rightmost number on the x-axis for that curve (thus, 1 indicates a family with 1 child, 2 indicates a family with 2 children, and so on through 9, which represents a family with 9 children). Studies of children from other populations showed more mixed results. Adapted from Zajonc (1976).

Detailed statistical analyses have supported the confluence theory. For example, this theory predicts that as later-born children get older, they should show fewer negative effects of birth order than they do when they are younger. (As their older siblings become more adult-like, the intellectual climate in the family is bolstered, which is predicted by the confluence theory.) In fact, analyses have shown that birth order effects do tend to decline as younger siblings age (Zajonc, 2001). It is important to stress, once again, that although they do seem reliable in very large data sets, these birth order effects are quite small, and it is not possible to predict intelligence differences on this basis in any single family.

Q: Describe two different models for the apparent relation between birth order and intelligence.

More surprising and striking than the potential impact of birth order on intelligence is the claim that birth order also predicts a personality trait related to rebelliousness, respect for authority, and conscientiousness. This link was first proposed by a historian of science, Frank Sulloway, who stumbled on what seemed to be a pattern among historical revolutionaries, in which firstborns were more likely to defend the status quo and reject radical change. By contrast, the later-born children were more likely to question and overturn traditions and norms (Sulloway, 1996). One study of 700 brothers who played professional baseball found that younger brothers were more than 10 times as likely to attempt to steal bases than were the firstborns. This observation is interpreted as a sports-related measure of risk taking, as attempts to steal bases are thought to more broadly reflect a tendency toward more radical behaviors (Sulloway & Zweigenhaft, 2010).

The effects in Sulloway's analysis are impressive and provocative—making other failures to find comparable personality effects in hundreds of birth order studies all the more puzzling (Harris, 1998, 2000, 2006). Some have argued that birth order influences on personality are highly context specific, affecting the way children behave toward their parents and siblings, but not generalizing to other situations as a broader personality trait would (Harris, 2006). Two arguments form a reply. One is that many studies that show no effects measure personality traits with self-report data, which may be less reliable than other types. Thus, some people who say they are "open to new experiences" or "welcome change" may really mean that they welcome change within the existing paradigm. The most telling data come from people's willingness to take real revolutionary action, as rated by judges who know neither the hypothesis nor the birth order of the individuals involved.

Such data are very rare outside of Sulloway's studies, but those that focus on real acts of rebellion seem to support his birth order prediction. One study examined 17 college students who had participated in civil disobedience as part of an ongoing labor dispute (Zweigenhaft, 2000). This small sample showed a significant relationship in which later-borns were more likely to have been arrested previously (and more frequently) for civil disobedience. A much larger study of 1,022 families in California and British Columbia found that siblings tended to describe firstborns as high-achieving and conscientious, while later-borns were called most rebellious, liberal, and agreeable (Paulhus et al., 1999). To see whether the participants were merely reflecting popular stereotypes about birth order, the researchers varied whether they emphasized birth order at the beginning of the questionnaires or whether it went unmentioned. This manipulation should have had large effects if the descriptions were based on popular stereotypes, but it made little difference in respondents' descriptions.

If the claimed birth order effects on personality do exist, on average, across large population samples, how might these effects come about? Sulloway and later authors (Paulhus et al., 1999) offered a model that closely resembles evolutionary notions about how different species compete for a particular biological niche. When a species takes over a particular habitat or food source within an ecosystem, it can force other closely related species to adapt to different niches. Similarly, these authors argue, firstborn children might tend to occupy certain typical family roles, thereby forcing their later-born siblings to seek out different niches. In their view, the firstborn is more likely to engage in behaviors that imitate parents (such as caring for the younger sibling) and will often be rewarded for it if those behaviors help the parents. They further argue that the firstborn is more likely to find that his acts of dominance and aggression against his siblings succeed, since the firstborn is physically bigger early on. These factors and others could make firstborns more likely to embrace their parents' values and more strictly uphold norms. By contrast, the later-born children, having been forced out of that niche, may tend to be more rebellious as well as more agreeable (since they are weaker at first).

Of course, such stories are easy to tell after the fact and difficult to test experimentally; but the notion of siblings forcing others to seek out contrasting niches is a powerful one that seems to fit many siblings' personal experiences. Recent studies of this phenomenon often use the term **sibling differentiation** to describe children's process of seeking out activities that resonate with their abilities and also reduce their competition with older siblings. Interestingly, siblings tend to get along better as they see themselves as occupying different roles in the family, rather than being in direct competition (Feinberg et al., 2003).

Q: What is sibling differentiation? How can it be used to explain the socialization patterns in a family?

An Interactionist Approach to Birth Order Effects

Even if these theories of birth order effects tend to hold true on average across large population samples, they undoubtedly interact with many other aspects of family life, producing enormous variations. As just one example, we saw at the beginning of this chapter that siblings' development can vary considerably depending on the socioeconomic status of the family (Conley, 2004). That is, siblings' future outcomes will be more similar when they grow up in families of high socioeconomic status, where parents do not have to make difficult choices about resource allocation (Conley & Glauber, 2005).

Parents from higher socioeconomic classes also tend to have more social capital, and this knowledge of social structures and professional contacts provides another advantage for their children. This might include knowledge about what sorts of schools and programs best prepare children for competitive colleges or what sorts of summer jobs offer an adolescent the best future opportunities (Furstenberg, 2005). Such differential social capital effects may be accelerating in societies where the gaps between the affluent and poor are increasing. These issues may have particular relevance to societies that have implemented policies trying to reduce family size (see Development and Social Policy box).

Parental resources can interact not only with family size but also with gender of children. For example, one study in South Korea found that when families have limited resources, there is an effect of family size on educational investments in girls, but little or no impact on boys (Kang, 2010). This gender difference was discovered by examining family expenditures on private tutoring for children, a practice seen as essential in many South Korean families for educational advancement. This finding presumably reflects the parental belief in South Korea that it is more important to invest in the educational future of sons.

More broadly, these sorts of findings suggest new levels of complexity to interactionist views. Researchers must consider how factors such as sibling spacing, birth order, sex, and family size interact with socioeconomic status of the family, cultural beliefs and practices, and whether that family belongs to a group that is stigmatized by the larger culture. By accounting for socioeconomic and cultural influences on sibling dynamics, researchers hope to predict more precisely when factors such as family size will significantly influence development.

Sibling Relationships and Socialization

Aside from birth order effects, which remain somewhat controversial, several other patterns of sibling interactions, including siblings' jealousy and conflict but also their degree of social understanding, may have long-term developmental outcomes. These interactions often involve parents and other important figures in a child's life as well.

Jealousy and Conflict between Siblings The birth of a new child can be especially upsetting to firstborns who are close in age to the new baby. This effect makes sense, given that parents do tend to devote less attention to the firstborn after the new arrival, try as they might to do otherwise (Dunn & Kendrick, 1982). Firstborns tend to react to this change by becoming more demanding of their parents. Sibling jealousy is also common and seems to vary in degree, depending on the children's age and their temperament. Among younger children, a reactive temperament is associated with more jealousy, whereas older children show more jealousy if they have poor emotional understanding (Volling et al., 2002). Moreover, siblings who perceive that parents treat them differently in terms of the resources they offer tend to have more difficult relations with one another and with their parents (Kowal et al., 2004; Reiss, 2001, 2003; Volling, 2012; Volling et al., 2010). A major goal for future research is to gain a better understanding of the circumstances that increase jealousy and competition between siblings and to find the best way to foster cooperation instead.

Conflict between siblings is not always based on jealousy, and it can be one of the most stressful aspects of family life. Although a moderate level of conflict can actually force siblings to negotiate more and increase their theory of mind skills (Howe et al., 2002), an excessive level exacts a toll on all family members. Many parents identify sibling conflicts as their worst family problem (Smith & Ross, 2007). Fortunately, parents can be trained to mediate sibling conflicts, and the training may also affect the children, who are more likely to learn how to resolve conflicts in constructive as opposed to destructive ways (Smith & Ross, 2007; see Scientific Method box). For example, after parents of 5- and 10-year-olds received mediation training, children of both ages compromised more often and seemed to understand their sibling's point of view better than a control group of children of untrained parents (Smith & Ross, 2007). Conflict resolution is a complex cognitive and social skill in which training can have strong, multifaceted, and long-lasting effects. In addition to conflict resolution, parental training and socialization of children should be concerned with prosocial behaviors in their own right (Kramer, 2010). It is an oversimplification to focus on sibling conflicts as the central dynamic among children in a family when in fact there are many positive dimensions of successful sibling relationships that can be influenced by parents as well.

Siblings and Social Understanding A positive effect for siblings, especially when they are close in age, is the development of more advanced theory of mind skills. Compared with only children or with those whose siblings are much younger or much older, siblings who are close in age are more likely to have practice thinking and talking about the mental states of others. This practice in turn may facilitate their understanding of the nuances of complex social interactions and the mental states of others (Jenkins & Astington, 1996; McAlister & Peterson, 2007; Peterson, 2000; Ruffman et al., 1998). Moreover, the more child-aged siblings a child has, the more theory of mind skills seem to be enhanced (McAlister & Peterson, 2013); thus, even if a large number of siblings may have some minor negative effects on intelligence test scores, it can have positive effects on social cognition. In a clear illustration of the intricate links between social and cognitive development, the early, consistent presence of others with similar interests and aptitudes apparently promotes the ability to think about other minds.

Sibling Relationships within the Family Besides the direct effects that siblings have on one another, their relations can involve the entire family in a web of interactions. For example, several studies have now shown that parents sometimes form expectations based on the firstborn child that strongly influence their interactions with later-born children (Brody, 2004; Whiteman & Buchanan, 2002). This has been called "the first child as the first draft" effect (Whiteman et al., 2003). Thus, a difficult first child may set up parental expectations that result in stricter parenting with younger siblings. These effects can even extend beyond the family when teachers make assumptions about how a child will perform academically based on how the child's older siblings performed (Georgiou, 2008; Rubie-Davies et al., 2006). On the other hand, parents' positive expectations can sometimes benefit later siblings. One study showed that when older siblings are both academically and socially skilled, parents tend to show higher self-esteem and better psychological functioning that translate into better parenting practices with later children (Brody et al., 2003). Intricate statistical analyses suggest that the older sibling actually *causes* changes in the parents that affect how the parents interact with younger siblings However, it is difficult to rule out other possible causes, such as shared genetic influences on parents' and children's personalities.

Much like the interactionist approaches to parenting research, studies examining the effects of siblings and family structures on development are becoming more sophisticated by increasingly taking contextual factors (such as relationship quality) into account. Consider, for example, the effects of sibling relationship quality on parents, parenting, and other siblings (Brody, 1998). As noted earlier, many parents identify sibling conflicts as the worst problem in their family (Smith & Ross, 2007). And when siblings are constantly at odds with each other, the likelihood of those siblings having problems with peers, poor performance in school, and general hostility increases (Smith & Ross, 2007). These correlations must be treated with caution, since a number of other factors could cause both the sibling conflicts and the other problems; but there is the real possibility that the conflict itself is corrosive to other relationships. Interestingly, siblings with similar temperaments tend to have fewer conflicts (Munn & Dunn, 1989). This finding was not immediately obvious, as some might think that siblings who play distinct, complementary roles in a family would be most compatible.

DEVELOPMENT AND SOCIAL POLICY

China's One-Child Policy

Children who are "only children" and have no siblings have been stereotyped in a variety of ways, some of them contradictory. They are sometimes seen as spoiled, unusually mature (or unusually immature), dependent, selfish, and socially incompetent (Silverman & Silverman, 1971). But are they really at greater risk for developing these largely negative traits? Although some early studies suggested problems in only children that accord with stereotypes, later reviews of the body of research found that only children show no systematic deficits (Falbo & Polit, 1986). This finding is reassuring given that in developed countries, many more families are now choosing to have just one child compared to a decade ago (Frejka & Sardon, 2007).

But what about cases where having an only child is not a voluntary decision but a nationwide decree? In 1979, the People's Republic of China laid down a set of regulations known collectively as the "one-child policy" (see Figure 14.11). These laws stated that every family was to have not more than one child. The goal was to prevent the widespread famines that had resulted in the past when China's food supplies fell short of its large population. Some exceptions to the one-child policy were granted, especially in more rural areas, but it generally accomplished its goal: China's birth rate fell and its incidence of single-child families greatly increased (Doherty et al., 2001). From 1980 to 2000, China's birth rate declined from roughly 35 children per 1,000 people each year to roughly 16 children per 1,000 people.

Have such dramatic and rapid changes in the structure of Chinese families caused developmental changes in children and young adults? This question has been of great concern to Chinese politicians and social planners, and many articles in the popular press have expressed worries about a new generation of "little emperors"—terribly spoiled, overindulged only children (Dean, 1992). Even in recent years, employers have posted job openings with the restriction that single children need not apply (Chang, 2008). In addition, 75 percent of China's urban couples reported that they would have preferred to have larger families, more like the ones they grew up in, and that they regard the one-child policy as a considerable sacrifice. Parents also worried that their children would be lonely without siblings and would miss out on critical social interactions (Tao & Chiu, 1985; Tung, 1997). A Chinese version of *Sesame Street* even included special segments aimed at teaching only children how to get along with peers (Tung, 1997).

Early studies of China's new generation of only children reported differences that followed the "little emperor" stereotype. Only children were said to be more spoiled and demanding (Jiao et al., 1986). These studies, however, were challenged by later ones that found no major differences in the behaviors or personalities of only children and other children (Chen et al., 1994; Falbo & Poston, 1993). Whether a child was the firstborn of several siblings or later-born, that child did not seem to differ in any systematic way from only children. In fact, in some studies, only children were found better adjusted than other children (Liu et al., 2010). Incidentally, these children with siblings were quite easy to find in China because certain regions were permitted fairly widespread exceptions to the one-child policy.

One explanation for this shift in research findings is that parents and grandparents concerned about having spoiled children

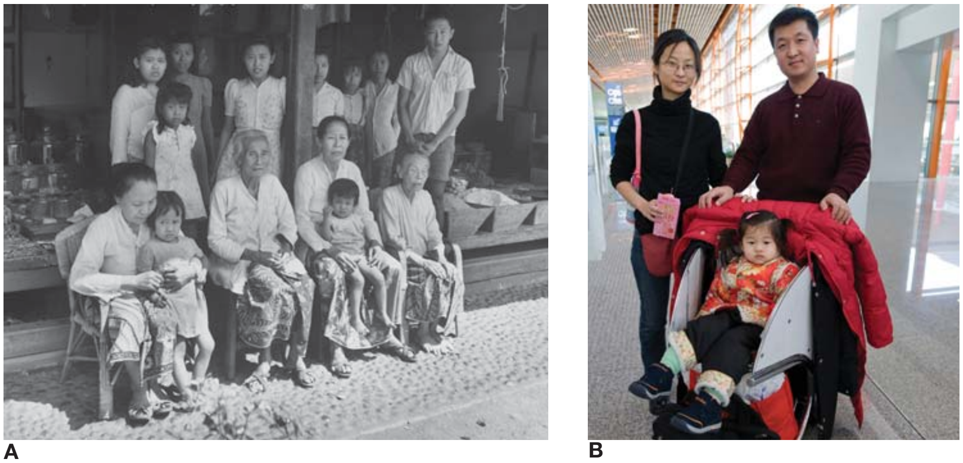

FIGURE 14.11 China's one-child policy. As can be seen from **(A)** a family photo taken in 1934 and **(B)** a recent family photo, family size in China has changed dramatically over the years as a result of China's one-child policy to manage a burgeoning population. Several commentators have argued that a nation of only children will grow up to be adults that are very different from those of earlier generations.

might have changed their child-rearing patterns (Rosenberg & Jing, 1996). In addition, as more Chinese children of the current generation spend increasing amounts of time in community day care from an early age, their interactions with peers may re-create some of the effects of siblings.

Although this second wave of studies did not show one-child effects, some effects may well exist, despite being difficult to pinpoint among the effects of other cultural and economic changes unfolding in China. In the last two decades, the one-child policy has brought a population shift in the cities from roughly 20 percent only-child families to 95 percent only-child families. Over the same period, the ways children spend their time has shifted from mostly being at home around relatives in the extended family to mostly being in day care. China has also seen improvements in the health and well-being of most of its people and a marked change in the political system and institutions of education. Any of these changes—let alone all of them at once—would likely affect children's social behavior regardless of our theory of socialization. The challenge for developmental researchers is that these large-scale changes have been so numerous and nearly simultaneous, making it difficult to untangle their cause-and-effect relationships without much larger and more systematic studies.

Some researchers argue that one-child effects can be found in behaviors other than those revolving around erroneous stereotypes of only children (Mancillas, 2006). For example, one study in the United States found evidence of a reduced ability to manage conflict with peers, perhaps because of less practice dealing with similar conflicts with siblings (Kitzmann et al., 2002). Comparable studies in China have yet to be done. As only children grow older, they may also have greater anxiety about having to be the sole caregiver of their aging parents, an obligation that is taken especially seriously in some Eastern cultures (Mancillas, 2006).

As the example with aging parents suggests, it may be that some of the effects of being only children take many years to manifest and may only be found in adults. This was the argument of one large-scale study of 412 Chinese adults who were born just a year or two before or after the one-child policy was implemented in 1979 (Cameron et al., 2013). The adults were studied in experimental tasks designed to assess trust, risk, and performance in competitive tasks. Children born in the first year of the one-child policy performed in these tasks in ways that were less trusting, less trustworthy, and less willing to take risks. Of course, the presence of such traits in laboratory tasks might not translate into real-world behaviors. Somewhat more naturalistic questionnaires after the experiments, however, also found strong effects, most notably less optimism about the future, less conscientiousness, and more neuroticism.

Demographically, one effect of the one-child policy is unmistakable, namely, a huge shift in the ratio of boys to girls in the general population. As seen in Figure 14.12, in rural areas there are roughly 25 percent more male than female births, the highest male-to-female sex ratio in the world, with some rural regions having 40 percent more male births (Zhou et al., 2011). A strong cultural bias toward boys has led to a reduction in the number of girls through abortion and infanticide. The psychological and social consequences of such uneven sex ratios are unclear, but they seem to cause many rural men to feel "useless, aimless, hopeless, miserable, sad, distressed, angry and lonely" (Zhou et al., 2011, p. 1426) as they consider their small chance for a future marriage. (To make matters worse, many rural men watch as their female peers leave for more affluent areas to find mates and "marry up.") These attitudes may start to emerge in late childhood and color the perspectives of many boys, especially those from more rural regions (Zhou et al., 2013).

The full effects of the one-child policy will require many more years to fully understand, but the situation helps to illustrate, once again, the critical importance of an interactionist perspective, where a huge confluence of factors must be considered to understand socialization effects and interventions that change traditional family structures. Regardless of the long-term effects of the one-child policy, it must ultimately be considered against a larger backdrop of a country burdened with overpopulation and a history of famines and other population-related disasters. Even the worst alleged psychological consequences of such a policy may pale when considered against the alternatives.

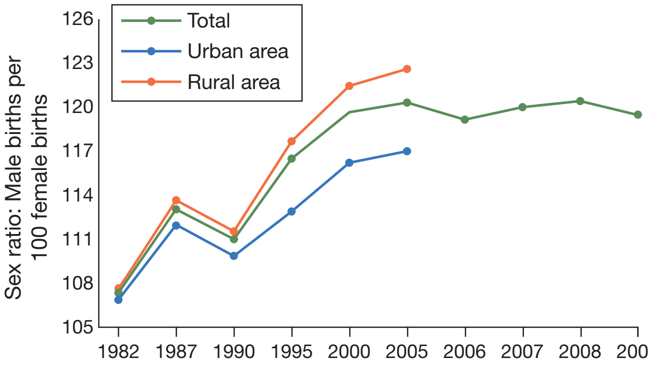

FIGURE 14.12 Sex ratios and the one-child policy. One effect of the one-child policy, especially in rural areas, is a huge shift in the ratio of boys to girls, which may well have a profound impact on social relations among peers. Adapted from Hvistendahl (2010).

SCIENTIFIC METHOD: Training Parents to Moderate Sibling Conflicts

Hypothesis:

Training parents to use formal mediation procedures helps them intervene in sibling conflicts between their children and reduce the intensity of those conflicts.

Method:

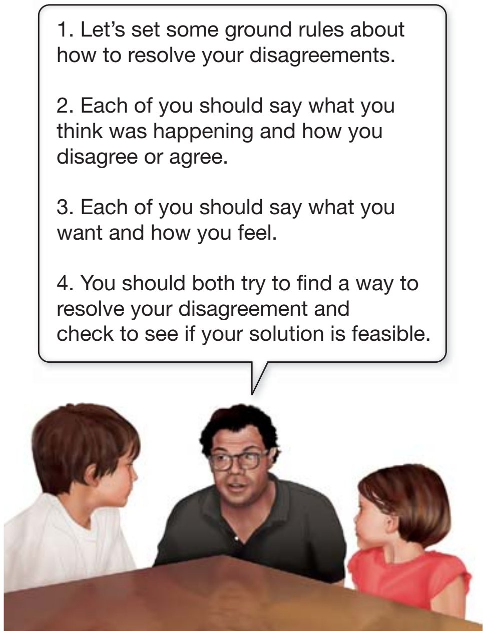
1. Forty-eight families with children ranging in age from 5 to 10 years old were randomly assigned to either mediation or control groups.
2. In the mediation group, parents were trained in a series of formal mediation techniques.
3. In the control group, parents were told that the study examined sibling conflict and parental interventions and were told to intervene normally.
4. Parents' reports of subsequent conflict episodes between siblings were recorded.

Results:

Siblings whose parents were assigned to the mediation group showed better conflict resolution strategies, compromised more frequently, and managed the outcomes of conflicts better. They also showed less negativity in recurrent conflicts, more nuanced assessments of blame, and greater ability to appreciate their siblings' points of view (see table).

Conclusion:

Training parents in well-proven mediation strategies for adults can reduce the intensity and tone of sibling conflicts both in terms of behaviors and in terms of social cognitive styles.



1. Let's set some ground rules about how to resolve your disagreements.
2. Each of you should say what you think was happening and how you disagree or agree.
3. Each of you should say what you want and how you feel.
4. You should both try to find a way to resolve your disagreement and check to see if your solution is feasible.

Frequencies of Conflict Resolutions

	Mediation Condition	Control Condition
Resolutions		
Compromise	74	40
Win/lose	6	27
Reconciliation	18	9
No Resolution	10	52
Who Resolves?		
Parent	11	74
Children	46	30
Children with parent's help	50	26

Source study: Smith & Ross (2007).

The interactionist approach to sibling dynamics sheds light on many developmental patterns and variations and suggests countless new research questions. Equally important, it is also powerfully relevant to practical developmental issues. For example, when children have to be removed from their parents' care and placed in a foster home following a crisis (such as serious child mistreatment), social agencies are often anguished about whether to compromise the quality of the foster care placement in order to keep all the siblings together.

Research on children in foster homes suggests an answer: siblings should only be kept together when they have a low-conflict relationship. In one study, siblings with significant behavior problems prior to placement in a foster home fared better after 18 months if they were placed in separate foster homes. In contrast, siblings who had positive relationships prior to placement did better if they were placed together in the same foster home (Linares et al., 2007). Clearly, policies that keep siblings together in foster home placements at all costs should be made more sensitive to the context and quality of sibling relationships.

Changes in the Family

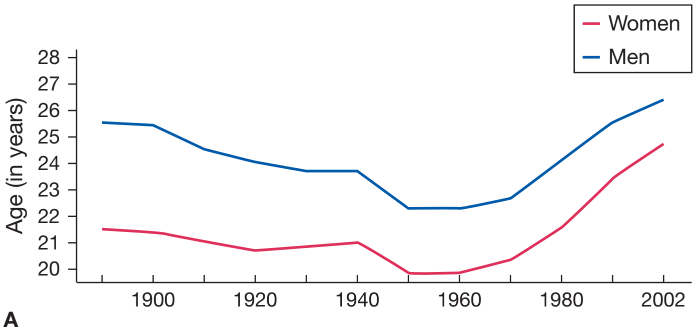
We have a tendency to think that "family" has had the same meaning throughout history. In fact, it is among the most dramatically changing concepts in the social sciences. Today's families differ in many respects from families in 1959, which were in turn different from families in 1910. From a psychological viewpoint, how have these differences influenced children's development? In this section, we will consider different kinds of families, including one- and two-parent families, small nuclear families and large extended ones, families with older versus younger parents, and families in which both parents work outside the home.

Changes in Parents' Age

Most people assume that the average age of parents in two-parent families has been gradually increasing over the last 100 years, but this assumption depends partly on the frame of reference. To be sure, the median age of marriage in the United States—which is closely related to parents' age when their first child is born—has risen in the past several decades. But as Figure 14.13A shows, looking at the median age of marriage over a longer time frame reveals that the recent rise is less marked than the striking drop that occurred right after the Second World War (Cherlin, 2005). This is a useful reminder that as dramatic as recent trends might seem, they should always be considered in terms of broader historical contexts. Nonetheless, in recent decades, maternal age at the birth of a married couple's first child has increased significantly throughout North America, Western Europe, and Japan (Cliquet, 2003; Mathews & Hamilton, 2009; see Figure 14.13B).

It is not completely clear why parents of newborns are getting older in many areas of the world, but one factor seems to relate to finances (Gustafsson, 2005). Many couples are postponing marriage until they have more economic resources, so that they will be able to support a child without having to cut back on their normal levels of consumption. As we will see shortly, older parents also tend to have smaller families.

What are the effects of delaying the childbearing years until the late 30s or even 40s? Although this question



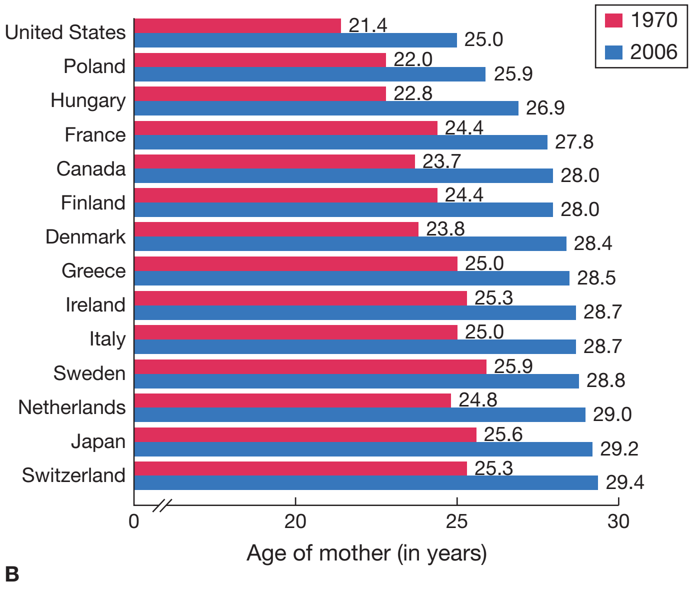


FIGURE 14.13 Median age of marriage and birth of first child over the last century. (A) The age of parents, which is related to the age of marriage, has risen dramatically in the past 40 years, but much of that rise is related to a return from a dramatic drop in the age of marriage that occurred after World War II. Adapted from Cherlin (2005). **(B)** Over the past four decades, however, whether the parents are from North America, Europe, or Japan, the mean age of mothers at the time of the birth of their first child has increased dramatically. Adapted from Mathews & Hamilton (2009).

has only recently been extensively studied, some provocative suggestions have come to light. One analysis suggests that older parenting brings tradeoffs for the children (see Figure 14.14). There is likely greater economic security for the family, but perhaps some negative social costs, such as greater psychological distance between parents and children (Martin, 2004). In general, scholars have emphasized the benefits of delaying marriage and childbearing, including more stable marriages, more elaborate networks of social support for the family, and parents' ability to provide more resources for the children (Gustafsson, 2005; Martin, 2004; Miller, 2011). Older parents also tend to interact with their children verbally in more sophisticated ways and to be less reactive. As always, though, it can be difficult to distinguish these effects from socioeconomic ones, since older parents are more likely than younger ones to be of higher socioeconomic status.

The downside of delayed childbearing is less apparent, but some effects seem likely. First, many children of older parents may have grandparents so old that they play only a marginal role, if any, in their lives, depriving these children of the benefits of a close relationship with their grandparents. These families may also be deprived of the kind of support that grandparents can provide to a family, such as providing day care, helping out in times of crisis, or simply being a mentor and source of expertise (Hayslip & Kaminski, 2005). Second, children report that they identify less with older parents, see them as more remote from their own lives, and feel less in tune with them. Research also suggests that older parents have less energy and more limited ability to engage in physical activities with their children (Martin, 2004). Finally, as seen in Figure 14.15, there are clear biological factors to consider, as the incidence of fertility and pregnancy complications increases greatly in the third and fourth decades of a woman's life (Heffner, 2004). This, in turn, can have a huge influence on family planning as well as creating additional stressors. In short, it will be important for future studies to systematically investigate the negative effects of late childbearing, as the answers concern increasing numbers of families.

FIGURE 14.14 Older parents. In many countries, parents are older when they have their first child. Being an older parent presents a number of tradeoffs in terms of its impact on children.

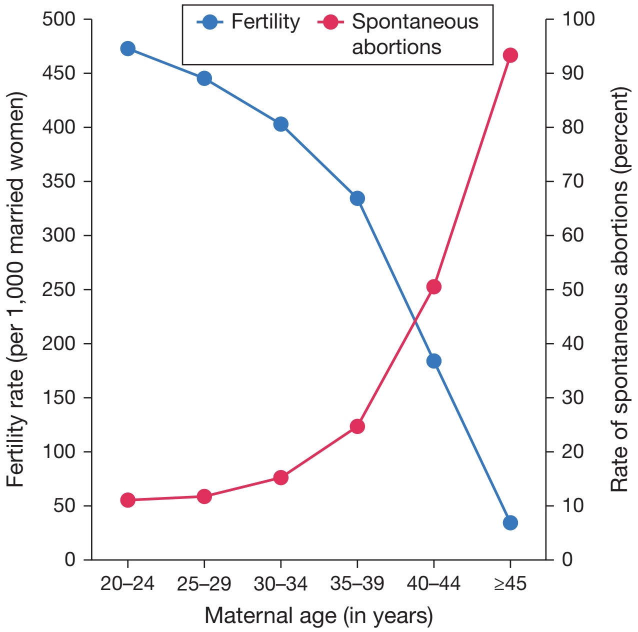

FIGURE 14.15 Age and motherhood. When women choose to have their first child at later and later ages, fertility rates and spontaneous abortions can change dramatically. Adapted from Heffner (2004).

Older parents are only part of the story of the changes in parental age in the last several decades. At the same time that parents in two-parent families are getting older, there has been a substantial increase in the number of single-parent families (U.S. Census Bureau, 2012a). Some of these single-parent families are headed by teenage mothers, although the rate of teenage pregnancies and the percentage of young teen mothers has decreased since the 1990s (Hamilton et al., 2012; Martin et al., 2012; see Figure 14.16). The net effect of these changes regarding parent age is to create an increase in two kinds of parents: those who are young and single and those who are older and have a partner.

What are the developmental effects of having very young parents—what some call the phenomenon of "children having children"? Several studies have reported that very young teenage mothers are at greater risk for depression, and their children are more likely to have academic and behavioral problems, such as acting out in school (Beers & Hollo, 2009; Pogarsky et al., 2006; Shaw et al., 2006; Sullivan et al., 2011). In these cases, however, disentangling causation from correlation is difficult. Very young mothers tend to be from lower income brackets than older mothers, are more likely

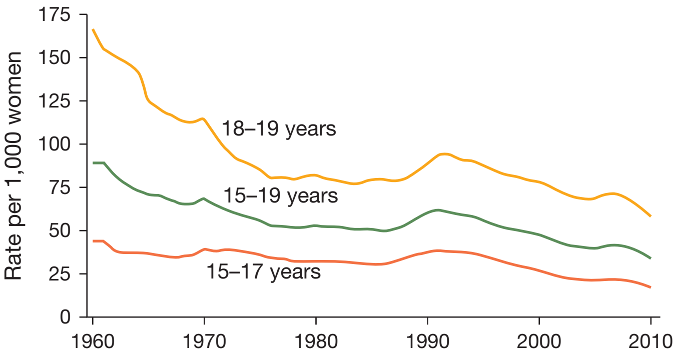

FIGURE 14.16 **Teen pregnancy rates.** Teen pregnancy and birth rates have been steadily declining for the last four decades. Adapted from Martin et al. (2012).

to be single parents, and tend to be less educated (see Figure 14.17). When researchers try to account for these other correlated influences, the effect of being a teenage mother per se often becomes smaller. However, when these other factors are controlled, children—especially boys—of teenage mothers still face a greater risk of negative outcomes (Olausson et al., 2001; Pogarsky et al., 2006). In many other cases, factors such as the mother's education level are so strongly linked to maternal age that it is difficult to examine the effects of maternal age separately from these associated factors.

Although the incidence of teenage pregnancy has declined in recent years in the United States and other countries, the statistics vary widely among racial and socioeconomic groups. The mean age of U.S. mothers when they first give birth ranges from roughly 29 for Japanese Americans and Chinese Americans to roughly 22 for African Americans, Mexican Americans, and Native Americans (see Figure 14.18). This increasing age for first births has been found in many parts of the world. In some groups, a younger mean age reflects a disproportionate number of teenage mothers. In short, although the number of very young mothers may be dropping overall, they still represent a large proportion of parents in some groups.

FIGURE 14.17 **Teenage mothers.** One major challenge, being met here by these teenage mothers in Brazil, is to continue schooling.

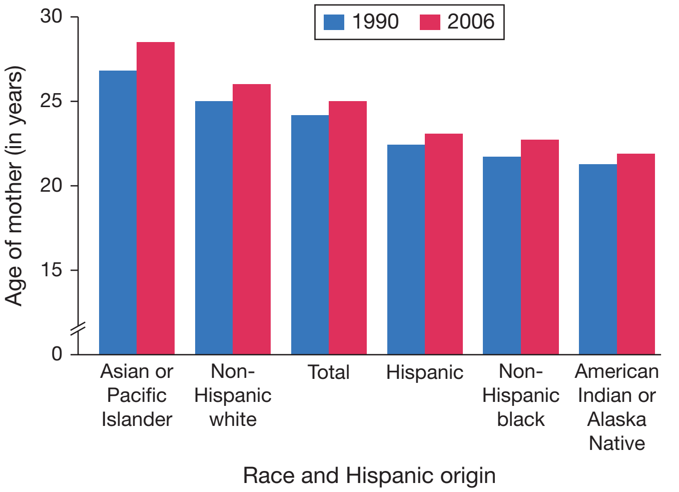

FIGURE 14.18 **Average age of mother at first birth for various groups.** For a diverse set of groups, the average age of mothers has increased in recent years. Adapted from Mathews & Hamilton (2009).

Changes in Family Size

In countries where the average parental age is rising, one consequence is a decline in family size. In addition, in many countries, factors independent of parents' age also contribute to smaller family size. Parents are choosing to have fewer children partly because of the economic burden of supporting more children and because the demands of caring for larger families is more likely to impinge on the parents' career aspirations (Miller, 2011). Average family size varies considerably in different countries, as Figure 14.19A shows. Most developed countries have seen a pattern of decreasing family size over the years. Yet even countries that are culturally very similar can show striking differences, both in average family size and in family size trends over time (see Figure 14.19B). In addition, within any given country, family size can vary considerably as a function of race and ethnicity (see Table 14.4). For these reasons, any statements about the developmental influence of changing family sizes have to consider the local cultural context.

It might seem that children in larger families would tend to have worse outcomes. After all, the more children there are in a family, the less economic resources and parental time and energy can be spent on each child, an argument that has been used to explain some sibling and birth order effects. On the whole, children from larger families do tend to receive fewer years of education and earn less money, and they are more likely to have disciplinary problems (Loeber & Stouthamer-Loeber,

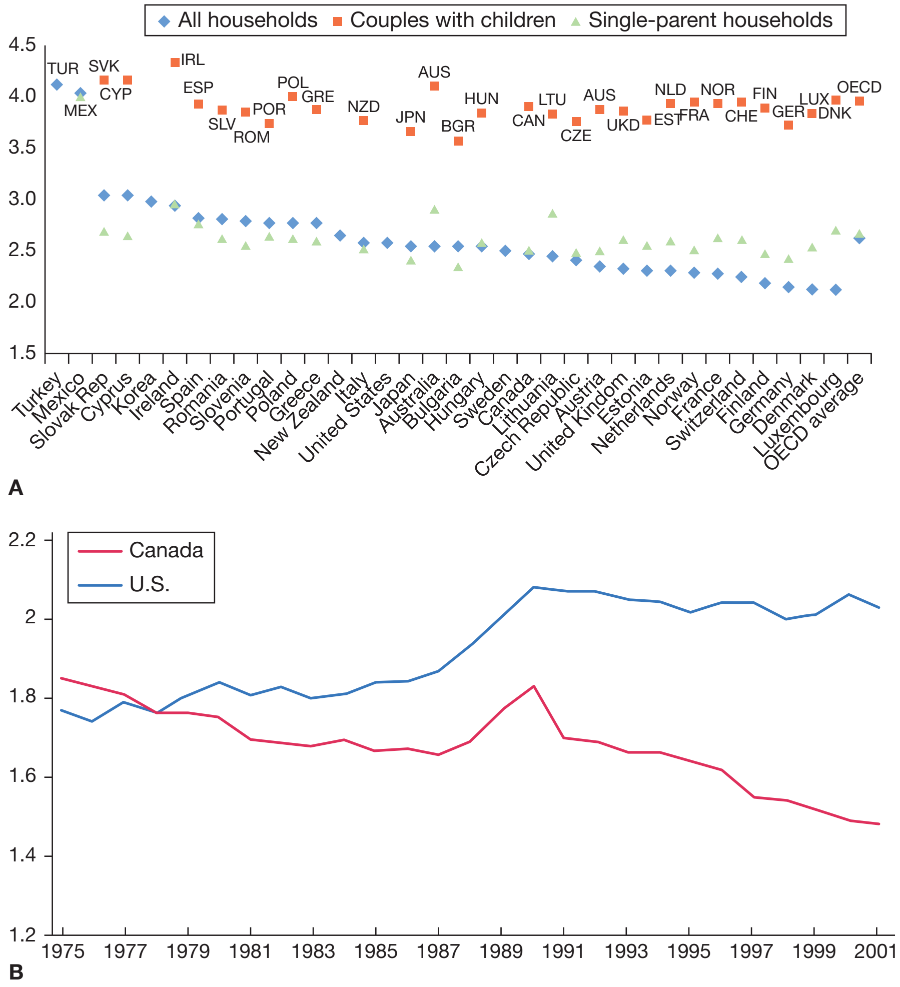

FIGURE 14.19 Family sizes in different countries. (A) Family size varies considerably across countries of similar levels of economic development. The graph depicts family size in the early and mid-2000s. Adapted from OECD Family Database (2010). **(B)** Despite the many similarities between the United States and Canada, these two nations are diverging rapidly with respect to average family size, as revealed by the mean total fertility rates from 1975 to 2001. Adapted from Eberstadt & Torrey (2005).

1986). But a closer look at these statistics reveals that family size is unlikely to be the main reason for these patterns. Family size is generally correlated with socioeconomic status: poorer families tend to have more children. Thus, in many cases, negative outcomes associated with large families may also be due to socioeconomic status. As mentioned earlier, family size may have negative effects primarily on poor families. For families that are not so poor, family size does not seem to negatively influence educational outcomes (Black et al., 2005). At the other end of the continuum, growing up as an only child does not seem to make children more spoiled or demanding, despite popular stereotypes (Chen et al., 1994; Falbo & Posten, 1993; Mancillas, 2006).

Another way of thinking about family size and structure involves the difference between nuclear families and extended families. **Nuclear families** generally consist of the mother and father as heads of the household, along with their children. **Extended families** reach across generations and sometimes incorporate aunts, uncles, and cousins. Often a grandfather or grandmother may be head of the extended

	Total Number of Households (millions)	Average Household Size	People under 18 in Household	People over 18 in Household
All	80.5	3.13	0.90	2.23
Hispanic	1.6	3.78	1.38	2.40
White	65.4	3.08	0.86	2.23
Black	10.0	3.31	1.16	2.15
Asian	4.3	3.40	0.92	2.48

TABLE 14.4 Family size and ethnicity in the United States. From U.S. Census Bureau (2012b).

family household. In many parts of the world, including much of Asia, extended families are the norm. Older parents may also have more of an impact on family dynamics in such cultures because if the parents are old enough, the grandparents may be too old to participate effectively.

Both kinds of family structures can have different positive and negative effects on children. Members of the extended family, and especially grandparents, can provide extremely important support to parents; in nuclear families, the sole responsibility for child-care arrangements more often falls to the parents. But extended families may encounter more disruptive transitions than nuclear families as grandparents age and family structure changes.

Working Parents and Child Care

Sometimes, cultural influences on families reflect changing socioeconomic realities. In Chapter 6, we considered the ways that day care arrangements might influence a child's attachment to his parents. In many countries, this issue is part of a much larger change in the number of families in which both parents work full-time outside the home. The incidence has increased in several Western countries over the past few decades (see Figure 14.20). For example, in the United States in 2012, 58 percent of mothers with a child under 2 years of age were employed outside the home (Bureau of Labor Statistics, 2013). In contrast, in the early 1950s, only 18 percent of mothers with a child under age 6 were employed outside the home (Halpern, 2005). The shift has primarily occurred among married women with a husband present in the household, as single mothers have worked at higher levels all along.

How has such a dramatic shift influenced the children in those families? Mothers who work outside the home might be spending less time with their children, which could have some negative effects. A few researchers have reported negative socioemotional effects, such as more difficulty in interpersonal relationships (Belsky, 2002; Belsky & Johnson, 2005; National Institute of Child Health and Human Development, 2003), but the vast majority of studies do not find any consistent effects, and when effects are found, they tend to be small.

In short, the shift to working outside the home by mothers does not seem to have had any consistently measurable negative impact on their children (Gottfried & Gottfried, 2006; Halpern, 2005). At least one study has shown that children of mothers working outside the home have no differences in educational achievements or in social or behavioral problems (Kalil & Ziol-Guest, 2008). One long-term study followed children up to the age of 24 and found no differences in occupational status at that age (Gottfried & Gottfried, 2006). Likewise, there is little reliable evidence that children's cognitive development suffers when mothers work outside the home (Burchinal & Clarke-Stewart, 2007).

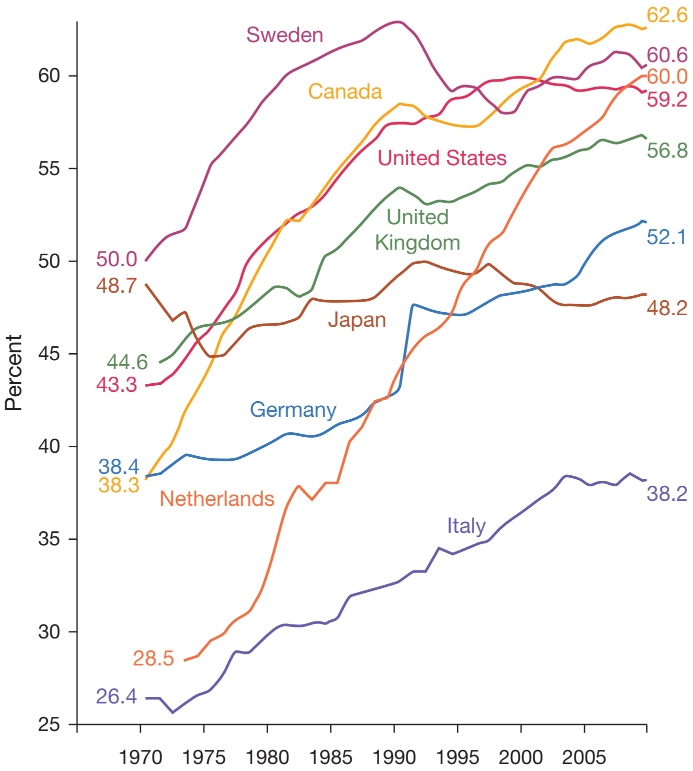

FIGURE 14.20 The rise of women in the workplace. Over the past three decades, there has been a sharp rise in the percentage of women in the workplace, although differences between countries remain very large. Adapted from the Bureau of Labor Statistics (2011).

There are several reasons why the effects of having two working parents seem small or nonexistent. Although some researchers found that employed mothers spend less time with their children (Gottfried & Gottfried, 2006), others found that by sacrificing leisure time, working mothers usually manage to spend just as much time with their children as those who are not employed. One line of research, in which mothers recorded their activities in detailed diary entries, carefully documented how these working mothers engaged in more multitasking and cut back on time doing housework in order to spend as much time with their children as mothers did in prior generations (Bianchi, 2011).

Indeed, one study found that working mothers during the period from 2003 to 2008 spent an hour *more* per week with their children than did stay-at-home mothers in 1975 (Bianchi et al., 2006; Fox et al., 2013). In addition, fathers are spending more time with their children as mothers spend more time working outside the home. As a result, today's children may actually spend more time with their parents than children did in prior generations (Halpern, 2005). Another reason why children of working mothers fare as well as other children may relate to the consistent finding that poverty negatively influences child development: when both parents work, their children are less likely to grow up in poverty.

Sometimes when both parents are working, there are negative effects on children. When mothers have nonstandard work hours, such as night shifts or erratic schedules, their children are somewhat more likely to show substantial delays in cognitive development (Han, 2005). One reason for such an influence is that parents who work nonstandard schedules have far more limited child-care options. High-quality center-based care, which has consistently been shown to benefit young children, is often unavailable to parents who need care in the middle of the night or on unpredictable schedules.

Finally, there are some suggestions that working women are often stretched to the limit more than working fathers (Porter, 2006). Many working mothers are using up every available nonwork hour, and they sleep almost 4 hours less per week than mothers who stay at home (Bianchi et al., 2006). Although no negative effects of such busy lives have been found, it is possible that for some working mothers, fatigue and burnout take a toll.

Changes in Family Structures

There are as many traditional family structures as there are cultural traditions, but in general, the recent changes in family structure in many developed countries include increases in single-parent families, families with same-sex partners, and families in which parents divorce and sometimes remarry.

Single-Parent Families Much attention has been focused on single-parent families, usually those with single mothers, since they are far more common than families headed by single fathers. Throughout the world, the percentage of single-parent families has been increasing over the past two decades (see Table 14.5). Because single-parent families are more common in lower socioeconomic groups and some minority groups, it can be difficult to know whether any adverse outcomes for children of single parents truly arise from having only one parent or whether they are largely due to other factors, such as economic hardship, and the ways they interact with other influences of single parenthood.

Low-income single parenting, for example, is strongly correlated with problems for children. One study examined differences between three groups of low-income parents: those who were single, those who were unmarried and living with a partner, and those who were married. Among these low-income groups, the single parents showed higher levels of mental and physical illness and drug abuse than those with other family structures, but these correlations are not evident for single parents with high incomes (McLanahan, 2004). Thus, financial stresses may be exacerbated by being a single parent, and vice versa.

Other studies examining a wider range of economic groups have found associations between single-parent families and children's educational and economic outcomes. On average, children of single parents tend to get fewer years of schooling and to earn lower incomes (Björklund et al., 2004). One intriguing analysis of African-American families suggests that single parenting is not associated with problems for children as long as another individual is also acting as an invested caregiver. For example, in many African-American families headed by a single mother, a grandmother serves as a second caregiver, providing critical support that reduces or prevents any negative effects of single parenthood (Simons et al., 2006), although later studies show that the positive effect of grandparents seems to vary as a function of contexts that are not yet fully understood (Arnold et al., 2011). In short, having a single parent need not have negative consequences for a child, but if that parent is also poor and lacks social support, there are increased risks for adverse effects.

In addition, the rates of single-parent families have varied dramatically across countries, over time, and across ethnic groups (Ellwood & Jencks, 2004; McClanahan, 2004). For example, a child born in the United States in 1995 was five times more likely to grow up with a single parent than a child born in Italy in 1995. Even larger differences exist within the United States: a child born into poverty or a disadvantaged minority group is seven times more likely to grow up with a single parent than a child born into affluence or in a more advantaged ethnic group (Hummer & Hamilton, 2010). The broad range of family structures that exist within many different cultural contexts therefore makes it difficult to generalize about the impact of family structures on children. More detailed and context-sensitive analyses are needed.

Same-Sex Parents A different kind of family structure involves same-sex caregivers (see Figure 14.21). There has been a marked increase in the number of gay and lesbian adults raising children over the past two decades. In 2005, approximately 300,000 children in the United States were living in families with two same-sex parents (Romero et al., 2007). When single gay and lesbian parents were included in a 2013 analysis, almost 2 million children in the United States were being raised by gay and lesbian parents (Siegel et al., 2013). These estimates are likely to increase considerably in future years in the United States and other countries where there is increasing social acceptance of same-sex couples and marriages.

One reason for increasing approval of adoptions by same-sex parents is that no negative outcomes have ever been consistently found for children of gay and lesbian couples when compared with children of heterosexual couples (Anderssen

et al., 2002; Chan et al., 1998; Patterson, 1992, 2013; Perrin, 2002; Siegel et al., 2013; Tasker, 2002, 2005). Children who grow up in gay and lesbian families do not differ from other children in their cognitive and social development or their incidence of behavioral problems. They also show the same profiles of sexual preferences, gender identities, and gender role behaviors. Some reviews suggest that children in gay and lesbian families may have more negative experiences than their peers associated with others' homophobia and stigmatizing of their parents, but even these negative experiences do not appreciably change child outcomes (Tasker, 2005). Indeed, at least one study reports higher levels of cognitive and social functioning and lower levels of behavioral problems among children of lesbian parents (Gartrell & Bos, 2010). One factor to keep in mind is that for most same-sex couples, the process of giving birth to or adopting a child is necessarily quite deliberate and involved, so same-sex parents have fewer unplanned or unwanted children. Moreover, same-sex couples, like all other couples who adopt children, have to pass assessments by adoption agencies and other social service organizations of their fitness as parents before they are allowed to adopt. Finally, many lesbian partners exercise choice in their selection of donors for insemination and may therefore be selecting for certain positive behavioral traits in fathers that are passed on to their children.

In short, although there are many popular stereotypes about problems associated with single-parent families and same-sex parents, the negative effects of growing up in either of these kinds of families are usually nonexistent. In

FIGURE 14.21 **Same-sex parents.** Same-sex parents have become more common in many parts of the world. Children of same-sex parents do not seem to have different psychological outcomes from children of different-sex parents.

the case of single-parent homes, negative outcomes for children more likely relate to other variables, such as poverty, that are not inherent to family structure.

Divorce Over the past few decades, the incidence of divorce has increased in several countries. In 1958, there were roughly 2 divorces per 1,000 individuals in the United States. This number rose rapidly in the following decades and peaked at approximately 5.5 divorces per 1,000 individuals in the 1980s, more than double the earlier rate. It has declined a modest amount since that time to roughly 3.6 divorces per 1,000 people (Centers for Disease Control and Prevention, 2013; Fields, 2003; Fields & Casper, 2001).

Approximately 40 percent of all children in the United States will experience a divorce and a transition to a single-parent family by the time they are 18 years of age (Amato, 2000; Cherlin, 2010; Kennedy & Bumpass, 2008). In the United States, over 1 million children are affected by a divorce every year (U.S. Census Bureau, 2012a). Beyond formal marriages and divorce, there also changes in cohabitation arrangements that may have similar effects. Such effects may be especially strong in the United States, where mothers are much more likely to change their cohabitation partners than are mothers in most European countries (Bianchi, 2011; Cherlin, 2010; Kennedy & Bumpass, 2008).

Divorce rates also vary as a function of social class and education, with increasingly higher rates among those who have fewer years of education (Bramlett & Mosher, 2002; Martin, 2006; see Figure 14.22). The reasons for this difference are complex but may be related to the average earlier age of marriage of those with fewer years of education. It is possible that younger couples are less experienced at dealing with the conflicts that can arise within relationships. Divorce rates also vary considerably across race and ethnicity. In the United States, the highest rates occur for non-Hispanic whites, followed in decreasing order by African Americans, Hispanics, and Asians, who get divorced at roughly one-third the rate of non-Hispanic whites. Again, the reasons for such differences are complex and are related to such factors as the overall rate of marriage, which is quite a bit higher, for example, for non-Hispanic whites than for African Americans (Fischer & Hout, 2006).

Divorce rates also vary considerably between countries. As Figure 14.23 shows, the U.S. rate is almost seven times that of Italy and considerably higher than that of several other countries, including Canada. These patterns often reflect cultural norms, which can also be reflected in laws and regulations designed to discourage divorce. They should not be taken as evidence that, for example, unhappy marriages are seven times more frequent in the United States than in Italy. These differences do show that the study of divorce and its

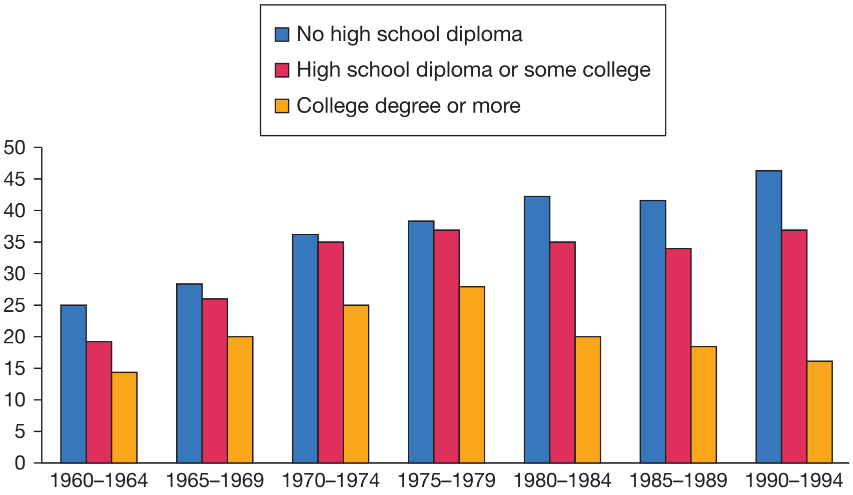

FIGURE 14.22 **Divorce rates and educational level.** Less educated parents are more likely to be divorced, a trend that has become more pronounced in recent years. Adapted from Martin (2006).

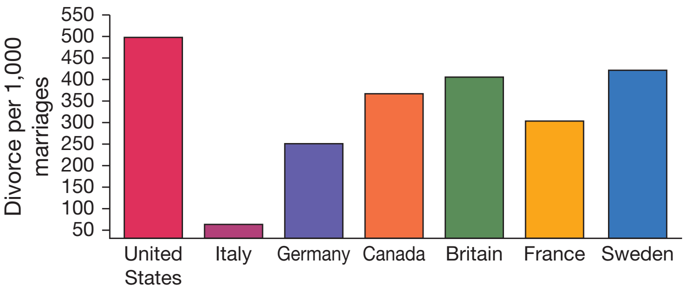

FIGURE 14.23 **Divorce rates across different countries.** Divorce rates can vary dramatically across different countries. Divorce rates reflect, among other things, the degree to which a culture's laws and moral norms oppose divorce, so a country's relatively high rate does not necessarily indicate that marital dissatisfaction is more common in that society. Adapted from Cherlin (2005).

impact on families must take into account many cultural settings rather than simply drawing universal conclusions from the preponderance of studies conducted in the United States. Nonetheless, because most major studies have been U.S. based, they will form the bulk of our discussion.

The central message here is that divorce patterns vary greatly across nations as well as socioeconomic classes and ethnic and racial groups within nations. Since there are so many divorce patterns, it is difficult to make many generalizations about the effects of divorce on children.

Q: Describe ways in which divorce rates vary across historical time periods in one culture and across cultures within the same time period.

Research on divorce has primarily focused on understanding its impact on children. This issue raises questions about differences in impact on boys and girls and on younger and older children. It also raises questions about whether different kinds of families (for example, extended versus nuclear families) and children (for example, only children versus those with several siblings) fare differently in divorce. Finally, it raises questions about tradeoffs. Is it better for the children of an unhappy marriage for the couple to stay together? Is it better for a child of divorced parents to spend equal time with each parent or to live primarily with one parent? Thousands of studies, not only by psychologists but also by sociologists, economists, anthropologists, legal scholars, and even evolutionary biologists, have examined divorce and its consequences. Many controversies remain, but a few fairly reliable patterns emerge, several of which may run counter to popular lore about divorce (Amato, 2010; Hetherington & Kelly, 2002; Hetherington & Stanley-Hagan, 2002).

First, the effects of divorce and their magnitude vary across studies, but divorce is generally associated with increased problems for children, potentially including declining school performance, delinquency, depression, aggression, and even increased health problems (Amato, 2010; Ellis, 2000; Grych & Fincham, 1992; Hetherington et al., 1985; Oldehinkel et al., 2008). One large-scale study of almost 1,500 families documented a wide range of behavioral problems reported by parents, teachers, and the children themselves (Furstenberg et al., 1983). Across many studies, it seems that the incidence of problem behaviors ranges from slightly more to almost double the rate for children of married parents. These increases are concerning, but their overall magnitude should not be exaggerated. Even doubling the average incidence of problematic behaviors means that only a relatively small minority of children in divorced families struggle with serious behavioral or emotional problems.

Q: What are some of the associations between divorce and behavioral problems in children?

Are the effects of divorce more detrimental for boys or for girls? The answer depends on the children's age and the particular problems in question. Among younger children of divorced parents, boys tend to show more behavioral problems than girls (Fauber et al., 1990). This is especially true when the child lives with a single mother, the most frequent post-divorce outcome in most countries. In these circumstances, young boys show more intense behavior problems than girls, and the problems arise sooner (Hetherington et al., 1985; Wallerstein, 1985a, 1985b; Warshak, 1992). For girls, the negative effects seem more pronounced later, during adolescence. They are more likely to be delinquent from school or excessively sexually promiscuous, in some cases even when the divorce occurred in early childhood (Allison & Furstenberg, 1989; Hetherington, 1991; Slater & Haber, 1984).

One difference between girls' and boys' responses to divorce, at all ages, is inherent in their trends for specific styles of coping reactions. Girls tend to show **internalizing problems**, which are largely within the individual, such as depression and loss of self-esteem. In contrast, boys tend to show **externalizing problems**, which are expressed by acting out in antisocial ways, such as bullying, underage drinking, and disruptive behavior in the classroom (Peterson & Zill, 1986).

Part of the complexity of the findings concerning different impacts on the sexes may also have to do with the gender of the single parent who remains with the child. This is yet another example of how, in any discussion of the effects of gender in families, the gender of both the parent and the child contribute to developmental outcomes. In most cases, living with a parent of their same sex seems to be better for the child; boys tend to fare better in single-father homes, while girls typically do better with single mothers (Camara & Resnick, 1988; Clarke-Stewart & Hayward, 1996). But this finding is complicated by the relative rarity of single fathers with custody of their children. These cases are roughly one-tenth as frequent as mothers with child custody. In fact, a large number of fathers interact very little with their children after the divorce. In one study, 20 percent of fathers interviewed reported not having seen their children at all in the prior year, and another 50 percent reported not seeing their children more than a few times a year (Seltzer, 1994). Thus, the relatively rare cases where fathers become the custodial parent may reflect the effects of atypical fathers rather than fathers in general.

The long-term nature of the effects of divorce runs counter to some commonly held views, which suggest that the effects taper off after a year or two. Even as adults, however, children of divorced parents are more likely to experience divorce in their own marriages (Amato, 1996, 2010; Amato & Booth, 1996; Cherlin et al., 1998; Hetherington & Kelly, 2002; Wallerstein et al., 2000). In some cases, and more commonly among women, divorce in childhood is associated with increases in depression and relationship difficulties when those children are adults (Kim, 2011; Wallerstein et al., 2000). In addition, parent-child relationships can suffer over the long term, with more deleterious effects usually occurring with fathers (Kalmijn, 2013). The mechanisms behind such long-term effects are unclear. They range from continued family stress to the power of early experiences to genetic predispositions shared with parents.

Q: How is divorce related differently to behavioral problems in boys and girls?

What is it about a divorce that causes the most problems for children? Several studies now suggest that explicit conflict between parents is especially problematic for children. It is often said that it is always better for the children if unhappily married parents divorce; but several studies suggest a more nuanced view that depends on the circumstances of individual families (see Figure 14.24). If the parents' difficulties do not erupt into overt verbal or physical conflict, there is some evidence that the children may fare better if the parents stay married, even if they are uncomfortable around each other or fairly detached from each other (Amato, 2006, 2010; Amato & Booth, 1996; Buchanan et al., 1991, 1996; Camara & Resnick, 1988; Emery, 1988; Katz & Gottman, 1993). As one extensive review points out: "Living in a marriage marked by mutual disengagement is a less-than-satisfying experience for parents. But . . . in these families, children have ready access to both parents, a standard of living based on both parents' income, and a predictable and stable home environment. Divorce in these cases appears to increase the risk of a number of problems for offspring" (Amato, 2006, p. 199).

FIGURE 14.24 Parental conflict. Overt conflicts between parents can have negative psychological effects on their children. Less overt tension or marital dissatisfaction does not seem to impact children as severely.

A stable family situation for the child can often be more important than parents first realize (Amato, 2010). But if the parents cannot avoid overt conflict, then the picture changes and the children are better off with one parent, providing that the post-divorce situation reduces the conflict (Amato, 2006, 2010). Of course, these conclusions cannot provide clear guidelines to a couple contemplating divorce. It may, for example, be difficult for parents to tell whether their disengagement from each other is stressful for their children. In addition, if parents' disengagement causes one or both of them severe distress, even if there is no overt discord, their distress may influence their parenting skills in other ways.

As divorce is usually a powerful, painful experience, it is natural to assume that the parents' divorce directly causes any associated problems in the children. But in many cases, a third factor, related to parents' and children's shared genetic disposition, may contribute to the difficulties that result in divorce and to the children's difficulties afterward. In the past decade, researchers have become increasingly interested in the genetic contributions to divorce and to the problems that affect some children of divorced families. One study of 398 adoptive and biological families with divorced parents found an intriguing interaction between genetic and environmental effects (O'Connor et al., 2000). The adopted children all had been adopted in the first few weeks of life. When the children were 12 years old, they and their families were extensively interviewed, and the children were assessed for a range of potential problems stemming from their parents' divorce. Based on these interviews and other assessments, the researchers examined five categories of potential effects of the divorce: changes in self-esteem, social competence (positive assertiveness and social responsibility), academic achievement, psychopathology, and substance abuse.

Notably, the differences in these categories were small between the adopted children of divorced parents and the children of divorced biological parents. Nonetheless, the children who were biologically related to their divorced parents seemed to show more negative effects from the divorce than did the adopted children. In particular, children of divorced biological parents showed more severe impacts on self-esteem, social competence, and academic achievement. The groups showed no differences with respect to more severe psychopathology.

These results support the idea that biological children and their parents share a genotype that both contributes to the difficulties that lead to divorce and makes the children more susceptible to problems as a result of the divorce. However, we should not regard our genetic heritage as strongly predicting our marital future. Indeed, some scholars have argued that shared genotype has a very limited role in explaining causal links between parental divorce and adverse outcomes in children (Amato, 2010).

Q: How can behavioral genetic models potentially help to explain associations between divorce and problems with children in divorced families?

Blended Families Given the high incidence of divorce and remarriage in countries like the United States, it is not surprising that there has also been a corresponding rise in blended families, created when parents remarry. **Blended families** consist of the parents and all children from their current relationship as well as children from prior relationships (see Figure 14.25). There are few reliable statistics on stepfamily configurations, but given divorce and remarriage statistics, it is safe to say that well over 10 percent of children live with at least one stepparent and that stepmothers are more common than stepfathers. Some estimates run as high as 30 percent if we include parents' cohabitation with new partners after a divorce (Bumpass et al., 1995; Radhakrishna et al., 2001). The increase in the incidence of these new kinds of families raises questions about how stepparents and stepchildren interact differently from the way parents and their biological children interact. Popular lore often condemns stepparents, and the theme of the cruel stepmother or stepfather is a frequent storyline in literature and folktales. Could there be any truth to the claim that stepparents favor their own children over their spouse's?

FIGURE 14.25 Blended families. Many children grow up in blended families in which all members thrive. In some cases, however, there are tensions with stepparents and stepchildren. In addition, some studies show that stepparents can be less invested in stepchildren.

Although there are millions of stepparents and stepchildren who have strong, loving relationships, the research shows some modest differences, on average, in the expected direction. Children tend to have more conflicts with their stepparents and less intimate relationships with them than with their biological parents (Furstenberg, 1987; Hetherington, 1999; Hetherington & Jodl, 1994). There is also a great deal of variation, though, and some studies find that children of divorced mothers who remarry fare just as well as those of divorced single mothers (Demo & Acock, 1996).

Other research, much of it spawned by claims from evolutionary biology, has argued that there are significant differences in how stepparents treat their spouse's children compared with their own biological children. One widely cited study reported that stepfathers abuse their stepdaughters more than 8½ times more often than biological fathers abuse their daughters (Russell, 1984). These findings and similar ones have been interpreted as showing that stepparents treat stepchildren more poorly because they have no genetic investment in them. According to this evolutionary argument, stepparents are less committed to their stepchildren's well-being because, unlike a parent's biological children, stepchildren will not grow up to pass along the stepparent's genes to the next generation.

These explanations have been a source of controversy (Adler-Baeder, 2006; Temrin et al., 2000), but most studies do suggest that stepparents tend to behave less positively toward stepchildren than toward their own children (Anderson, 2011; Gardiner & Björklund, 2007). Some of the more interesting analyses of parental investment concern the subtle ways that parents treat children differently. One analysis of investments in college education in two-parent families found a difference in relative financial contributions between households with two biological parents and those in which one or both parents also had stepchildren. Stepparents started college savings accounts later, put less money aside, and expected to pay less than biological parents did for the first year of college (Zvoch, 1999). This pattern occurred even when stepparents and biological parents were of equal socioeconomic status and income level. Other researchers have found similar patterns (Anderson et al., 1999a, 1999b).

Another study found that stepchildren tended to be physically shorter than biological children (Flinn et al., 1999), a finding that gains some plausibility from other evidence that stressful environments can affect a child's height (Eiholzer et al., 1999). Even doubts about paternity can have an effect. A father's degree of confidence that he is the biological father of a child has been related to how much time he spends with that child (Anderson et al., 2007). At the same time, the effects in these studies are generally small. Many interacting influences bear on a child's development, and most stepparents by themselves do not exert a dominant effect on a stepchild's future.

There also seem to be some sex differences in the effects of stepparents on children's emotional development. Boys sometimes benefit from the presence of a new father figure, while girls, especially adolescents, often seem to have an increase in problems with the arrival of a new father in the house (Hetherington, 1989; Hetherington et al., 1985; Hetherington & Stanley-Hagan, 2002; Zimiles & Lee, 1991). Both boys and girls tend to have more difficult relationships with stepmothers (Hetherington, 1999). One possible reason for the problem with stepmothers is that fathers in such families often expect the stepmothers to take over the role of the more "full-time" parent, while mothers do not tend to have similar expectations of stepfathers. Children may resent it when a new stepparent suddenly becomes the more dominant parenting figure (Hetherington, 1999).

Q: Describe at least two distinct forms of evidence that stepparents may treat their children differently than biological parents.

Child Abuse

Sadly, parents do not always provide healthy, or even benign, environments for their children. Throughout the world, some parents inflict serious harm, which can take the form of physical abuse, psychological abuse (usually in the form of verbal attacks), or sexual abuse. The abuse may involve taking physical action against a child, but neglect of the child's physical or emotional needs can also constitute abuse. The question of which psychological factors can lead a parent to commit abuse is more suited to a discussion of adult psychopathology than to developmental psychology. Here the central question concerns the impact of abuse on children.

First, consider some statistics about the prevalence and patterns of child abuse in the United States. One data collection reported that almost 750,000 children were victims of maltreatment each year, a rate of roughly 10 per 1,000 children in 2011. In this group, roughly 20 percent suffered from physical abuse, approximately 10 percent from sexual abuse, and almost 60 percent from various forms of neglect (U.S. Department of Health and Human Services, Administration for Children and Families, 2012). These numbers come from cases that were reported and officially recorded by an agency. It is widely assumed that many cases of abuse are never reported, as parents fear being prosecuted and children often fear both parental retaliation and abandonment.

Abused children are generally young—most are less than 3 years old—and the incidence of physical and verbal abuse is roughly equal between the sexes, although girls are four times more likely than boys to be sexually abused. Moreover, abuse is highly likely to recur. Children who are reported as abused once are much more likely than other children to be reported as abused in the future, even when agencies attempt to monitor the situation and prevent recurrences. Victimization rates in the United States differ across ethnic groups, most likely because poverty and other stresses on disadvantaged groups greatly increase the likelihood of abuse and neglect. Overall, roughly 60 percent of the people who abuse children are female, usually the mothers. In the case of sexual abuse, however, the abuser is much more likely to be male and the father. These, then, are the raw statistics. The critical developmental questions concern how these patterns of abuse are set up and maintained and how they affect children. Another key question is what sorts of interventions can reduce the incidence of abuse.

Q: Describe some examples of how child abuse patterns seem to vary across population groups. How might these differences be explained?

Effects of Abuse

There is an extensive body of research investigating how abuse affects children, both in the short term and later on in their adult lives. In general, all forms of abuse have substantial negative effects on children of both sexes, but the size of these effects varies enormously across studies (Dallam et al., 2001). The field is emotionally charged to an extraordinary extent, as most adults find child abuse, especially child sexual abuse, to be so morally repugnant that they find it difficult to remain neutral about claims that seem to minimize its long-term negative effects. Indeed, the gut feeling against abuse is so strong that it may be subject to moral dumbfounding of the sort described in Chapter 12. A similar outrage in many scientists makes it difficult to objectively design and interpret studies. Even with those cautions, however, most studies do point to the same kinds of negative effects.

The effects vary somewhat across the aforementioned categories of abuse: physical abuse, psychological abuse (usually in verbal forms such as sarcastic and demeaning remarks), and sexual abuse. A fourth category is neglect. For infants and toddlers, all forms of abuse are associated with insecure attachments. Older children who are physically and psychologically abused show more aggression starting as early as preschool. The aggression continues throughout adolescence, often becoming increasingly severe (Aber et al., 1989; Allesandri, 1991; Beitchman et al., 1991, 1992; Boney-McCoy & Finkelhor, 1995; Gross & Keller, 1992; Hart & Brassard, 1987; Kendall-Tackett et al., 1993; Malinosky-Rummell & Hansen, 1993).

Children who are sexually abused show different patterns. Those who have been chronically, severely sexually abused show insecure attachments early on, followed by a spectrum of both internalizing problems, like depression and anxiety, and externalizing problems, such as substance abuse (Bouvier et al., 1999; Browne & Finkelhor, 1986; Finkelhor et al., 1990; Fleming et al., 1999; Mullen et al., 1994). There is some controversy over the relative impact of childhood sexual abuse on boys and girls when they become adults, but the evidence suggests perhaps a more prolonged and severe impact on girls. An important caution to keep in mind, however, is that much of the data are collected by interviewing adults about their psychological status. If men are less willing than women to disclose psychological problems to an interviewer, the data on sex differences will be skewed. Most of these studies have also been done with college students. But there is good reason to believe that many of the individuals most severely affected by abuse would never make it to college; consequently, they would not be included in the samples, thus reducing the apparent effects (Dallam et al., 2001).

One major problem in child abuse research involves appropriate ways of controlling for factors in abusive families, other than the abuse itself, that affect children's development. Abuse of all forms is more common in families that also show other dysfunctional patterns, making it difficult to distinguish the effects of abuse from those of other forms of dysfunction (Boney-McCoy & Finkelhor, 1996). Moreover, if common genetic predispositions influence such traits as low impulse control, then the same traits that lead parents to abuse may also lead their children to act out impulsively or show other kinds of behavior problems.

Q: What are some of the challenges in trying to understand the psychological effects of abuse on children?

Explaining the Cycle of Abuse

These issues come to the fore in considering different theoretical approaches to the causes and consequences of child abuse. All of these approaches try to address one of the most tragic aspects of child abuse: its tendency to recur in ensuing generations of the same family line, often known as the **cycle of abuse** (Egeland et al., 1988). One possible explanation for the cycle of abuse builds on attachment theory, suggesting that abuse creates insecurely attached children who, as a result of being insecurely attached, grow up to behave toward their own children in a way that fosters insecure attachments. This attachment style could then increase the odds of negative parent-child interactions and abuse (Egeland et al., 1988). Other explanations invoke a social learning perspective, arguing that children learn to model their parents' behaviors. In this view, abused children go on to re-create, in their own families, the abuse they have observed and experienced (Bandura, 1971).

Environmental explanations argue that the stress of living in poverty, along with the attendant risks of crime and drug abuse, sets up a context in which parents are more likely to abuse their children. This effect might be further exacerbated in single-parent homes, where a second parent is not around to buffer the occasional lapses of the other. Thus, the immediate household environment and the larger-scale community in which a child lives may both increase the chances of abuse. In addition, some argue that a culture that emphasizes corporal punishment might make it easier for parents to cross the line from physical punishment to abuse (Gershoff, 2002; see Figure 14.26).

In contrast, a behavioral genetic view would argue that a cycle of abuse continues because both parents and children have genetic tendencies to be aggressive, impulsive, or likely to commit some other behavior that creates a climate of abuse. The most extreme version of this view claims that these inherited tendencies will express themselves regardless of experience. The more nuanced and more common genetically based view holds that some genetic factors put individuals at high risk of becoming abusive if they are exposed to certain stressful or aversive environments that would be much less harmful to others.

It is critical to note that any and all of these factors interact; they are not mutually exclusive. Even so, understanding which factors are most influential would have a huge impact on attempts to break the cycle of violence and abuse. Currently, programs throughout the world attempt to solve the problem by focusing on improving the attachment relationship, by modeling more positive behaviors for parents and children, and by alleviating environmental stresses that might make abuse more likely. Applying the behavioral genetic approach is a more complex proposition because it requires theories about the ways that specific genes interact with other variables to increase the risk of abuse.

FIGURE 14.26 Corporal punishment and child abuse. Although many cultures endorse some degree of physical punishment as part of child rearing, some researchers regard corporal punishment and physical abuse as running along a continuum on which the appropriate line can be difficult to draw.

Studies show that the variety of interventions that attempt to reduce child abuse have mixed results. There are some significant success stories, but many other cases show little reduction in violence. More systematic research on the factors that contribute to the cycle is essential to develop reliable, highly effective interventions.

Q: How do cycles of abuse perpetuate abuse across generations?

Foster Care

When children are considered to be at serious risk of abuse, they are often removed from their parents and assigned to live with a foster family. Children in foster care may have a series of foster families, either until they reach maturity or until it is considered safe for them to return to their biological family. In the United States, the number of children in foster care grew from approximately 276,000 in 1985 to 568,000 in 1999 (Swann & Sylvester, 2006). This estimate has since declined somewhat to roughly 424,000 in 2009 (Child Welfare Information Gateway, 2011). The proportion of children in foster care is not evenly distributed across ethnicities, with disadvantaged minorities having a larger proportion in foster care (see Figure 14.27).

It is difficult to measure the extent to which foster care influences children's development (see Figure 14.28). In addition to the tremendous range of foster care situations, most of the children in foster care are there because they have suffered some sort of trauma. It is therefore not surprising that children in foster care tend to have more psychosocial problems than children who grow up in their birth family homes. Children also commonly move in and out of foster care. Roughly half the time, they end up reuniting, at least temporarily, with their birth families (Chipungu & Bent-Goodley, 2004), making it difficult to estimate the effects of foster care itself.

One provocative study conducted in Minnesota looked at three groups of children: 46 children who entered foster care primarily because of child maltreatment, 46 who endured maltreatment but remained at home with the maltreating caregiver, and 97 who were not maltreated and not put into foster care (Lawrence et al., 2006). All three groups of children were from poor families with young mothers. At the beginning of the study (and before any of the children were placed in foster care), all of the children were assessed for attachment quality, self-control, and emotional health.

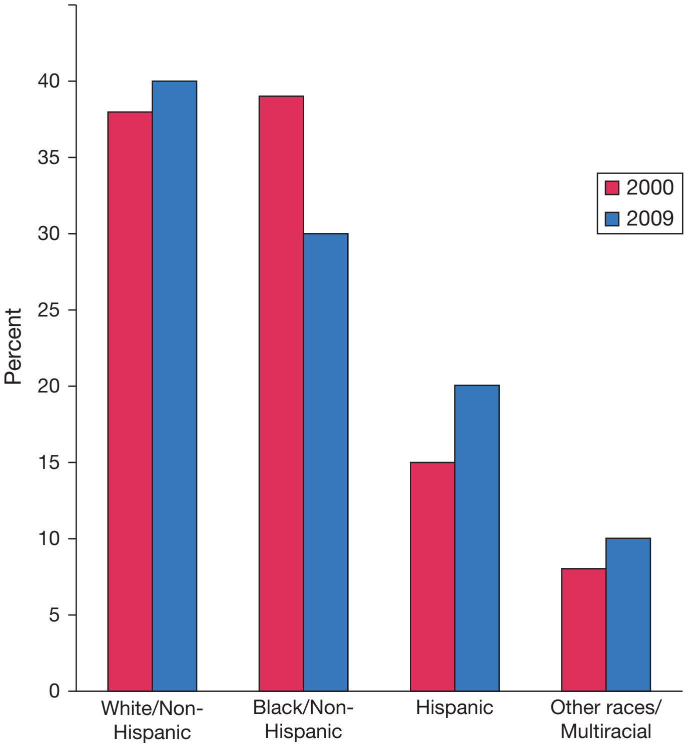

FIGURE 14.27 Race and ethnicity of children in foster care. The incidence of children in foster care in the United States has increased over the past decade in all groups except African Americans, who have shown a substantial decline. Adapted from Child Welfare Information Gateway (2011).

At this point, both groups of maltreated children—those who would enter foster care and those who would remain at home—showed similarly high levels of many kinds of behavior problems compared with the control children. After spending time in foster care, that group of children showed more behavioral problems than the children who remained with a maltreating parent. These problems continued for many years after the children left foster care and as they became young adults.

This study has its limitations, however, even with the considerable methodological care taken by the researchers. For example, when maltreated children stayed in their parents' homes rather than entering foster care, there was likely something about their home life or their family relationships that convinced social workers that they could safely stay in their homes—something that was not true of the families whose children were placed in foster care. The preplacement data showed comparable levels of problems between the two groups of maltreated children, but these more subtle family differences may still have affected the children's development.

As seen earlier in this chapter, the effects of foster care also interact with how siblings get along with each other, such that low-conflict siblings should be kept together in foster placements, but high-conflict siblings are better off when placed in different foster homes (Linares et al., 2007). Several additional, carefully designed studies will be needed to understand when it is better to place a child in foster care rather than allowing him to stay in a problematic home. Clearly, another central issue in this area of research is the need to develop better ways of characterizing different kinds of foster care situations to understand which types will more often lead to developmental problems and how those situations interact with the internal dynamics of the families at risk.

FIGURE 14.28 Foster care families. Throughout the world, many children spend part of their childhood growing up in foster care families, which may consist solely of foster children or be a blend of the foster parents' biological children and foster children. Foster care families vary greatly in terms of the kind of environment they provide, and there is ongoing concern for those children being raised in substandard foster care settings.

Conclusions

An understanding of the child's role in the family seems to invoke a different sort of approach from those used in earlier chapters. Many different theoretical approaches can be used to examine the associations between behavioral and psychological patterns in children and those in their parents and siblings. The focus of these theories ranges from social learning effects, to behavioral genetic forces, to attachment-based dynamics, to environmental influences. As we have seen, in many cases, all of these factors are at work, making the job of sorting out causes from mere correlations extraordinarily complex. Given the numerous interacting influences that affect family dynamics, we cannot simply ask a question such as how much parents matter. Instead, we must ask how parental influences interact with the child's disposition, the local environment, and the particular aspects of child development under investigation. The surrounding culture can be critical as well. What constitutes harsh, unyielding parenting in one culture may be seen as a normal, caring style in another.

This complex web of interactions can be difficult to disentangle, but the best work manages to conceptualize and empirically uncover stable, widely applicable patterns. These patterns often take the form of interactions between types of parents, types of children, and types of behaviors. For example, we saw that research on the effects of divorce points to a pattern of effects that interacts with the gender of both the parents and the children. That same pattern of effects is also influenced by the children's age—both when the divorce occurred and the age of the child when the potential effects of the divorce are studied. From this set of interactions, reliable patterns have emerged that can be used to make interventions more effective for children struggling to cope with their parents' separation. Similarly, some studies suggest that teaching parenting skills can have positive outcomes for children, although it is not always easy to obtain long-term positive effects from such interventions. Finally, research on foster care is starting to help social workers and other professionals understand when and why it is important to keep siblings together in foster family placements and when it is better to keep them apart.

The social policy implications of research on the family are far too important to let larger patterns of cause and effect go unexplained. We see once again how viewing development as an active exploratory process is so important for understanding many aspects of the role of the child in the family. For example, the idea of child effects as explaining links between parenting and children's behaviors is closely linked to a perspective that sees the child as an active, influential participant in the process of socialization in the family (Grusec, 2011). It also fosters a view of parents and children as frequently becoming intertwined in interactive feedback loops, rather than seeing the child as a passive recipient of parental influences. We also see in many ways how social, cognitive, and personality development are interwoven in understanding many causal patterns within the family. For example, gender roles are related to children's beliefs about themselves and others, to interaction patterns between parents and children, and to the particular personalities of all participants. Similarly, sibling conflicts and jealousy within the family can only be understood by considering cognitive capacities, social interactions, temperament, and personality in all their interactive richness. As research models become better able to take all these causal patterns into account, social policy decisions will be correspondingly better informed.

STUDY AND REVIEW

SUMMARY

Parenting

- Parenting involves many different kinds of behaviors that support a child's development, including nurturance, discipline, teaching, language use, providing toys and educational materials, monitoring children's behavior, and time management. All of these behaviors vary, depending on the family's culture and socioeconomic status.
- Parents in Western cultures show quite distinct parenting styles. Diana Baumrind and her successors described four styles—authoritarian, permissive, authoritative, and neglectful/uninvolved. These styles differ in terms of the level of warmth and responsiveness that parents show to their children and in their level of demands or control.
- The authoritative style is more strongly correlated with positive outcomes in children, leading many to draw the conclusion that parenting style causally influences the child's personality and other factors. Although some studies have suggested a causal role for parenting style, that conclusion must also be tempered by other influential factors, such as child effects, shared genotypes between parent and children, and the influences of local environments and peers.
- The influences of particular parenting styles seem to be highly culturally specific. Children in different cultures may interpret the same parental behaviors very differently, resulting in very different outcomes for the children.
- Interventions to improve parenting seem to help both parents and children with their relationships when the programs are designed carefully and with sensitivity to the particular group of children at risk.
- Parenting is not the only way to explain a child's personality and behavior. Children themselves produce effects in parents and others, which set up feedback loops of interaction

between parents and children. In addition, parents' and children's shared genetic bases for some behaviors may account for some similarities in ways that go beyond the influence of parenting practices. Parenting may be less important to understanding how a child's personality takes shape than it is in understanding the kinds of experiences to which a child has had access, such as sports teams, clubs, and shopping venues.

- In the end, an interactionist view of parenting seems most useful as a way of understanding the variety of influences that guide children in development.
- Gender socialization is a complex process involving a web of interacting influences. Parents tend to offer gender-stereotyped toys and to engage boys in more physical activities and girls in more conversational ones. Yet, children themselves also affect this process, often showing strong gender-stereotyped toy preferences before the age of 2. One facet of these early biases has been linked to hormone exposure before birth. For girls, a higher level of testosterone exposure in utero correlates with preferences for more stereotypically male toys. Research into sibling effects on gender role qualities suggests that parents' influence is strongest on older siblings, who then propagate those roles to younger siblings.

Siblings and Family Dynamics

- In families with more than one child, each child's position in the family may have developmental effects. Firstborn children appear to have richer and more stimulating environments. This may give them a slight edge in intelligence even when other factors are controlled. Other indications suggest that later-born children may be more rebellious and willing to challenge the status quo, although it is unclear whether these effects are reliable and whether they apply only in specific circumstances.
- Siblings can also affect one another more directly. Jealousy and conflict between siblings can take a toll on the whole family, but when parents are trained to mediate these conflicts, children often show a corresponding tendency to resolve the conflicts constructively. Siblings who are close in age may accelerate one another's development of theory of mind. There is less clear evidence that being an only child has distinctive effects, despite popular claims of negative effects.

Changes in Families

- Families are changing in many ways. On average, parents are having children at an older age and are having fewer children, and in many cases, both parents work full-time outside the home. Over the last few decades, a number of changes in the family structure have also become more common, including single-parent families, families with same-sex parents, and families in which parents have divorced and perhaps remarried. These patterns vary dramatically, both across cultures and across socioeconomic and ethnic groups.
- Children may be affected by family size and by living with single parents or working parents. But these effects are often subtle and interact with factors such as a child's socioeconomic status.
- Divorce does seem to increase the odds of problems for children, ranging from internalizing problems (such as depression) to externalizing problems (such as increased aggression or sexual promiscuity).
- When parents remarry and families become blended, other problems may emerge as well. Evolutionary theory predicts more problems between stepparents and their nonbiological offspring. There is some evidence in support of that prediction.

Child Abuse

- Physical, psychological, and sexual abuse of children occurs at alarming rates; recent data show that approximately 10 per 1,000 children were victims of some form of abuse in 2010, and most abused children are younger than 3. Abuse is more common among the poor, most likely because the stresses of poverty increase the chances of child maltreatment.
- The effects of abuse on children vary considerably between studies. One consistent pattern is that physical abuse and psychological abuse seem to have different effects than sexual abuse.
- Cycles of abuse, in which children of abusive parents go on to abuse their own children, may be caused by multiple factors. These factors range from the children replicating parenting practices, to the effects of adverse environments, to shared genotypes between parents and children that are correlated with abusive behavior phenotypes.
- Children are usually put into foster care when the situation in their own biological family has high levels of abuse and when no other placements with relatives seem feasible. Foster care arrangements vary widely, with some being associated with adverse consequences for children. This is especially true when there is little long-term stability and sibling relationships are not taken into account.

THOUGHT QUESTIONS

1. Should future parents be asked to get parenting licenses? In most of the world, a teenager who wants to drive a car must pass a test of driving proficiency before he or she is allowed to drive. Some have argued that societies should also have "parenting" licenses wherein a prospective parent must take a course and pass a test to receive such a license, as the consequences of being a poor parent are much worse than those of being a poor driver. Evaluate such a view in light of research on parenting.
2. Foster home care has mixed results because the quality of care varies so greatly and because some foster children have no stable home. Sometimes foster children shift between more than a dozen homes as they grow up. Should local or

state governments greatly increase the size of public facilities where children might spend their time growing up in the same residence and surrounded by the same people?

3. Many states have required waiting periods for couples contemplating divorce. Imagine that a state legislator proposes doubling the waiting period for couples with children under the age of 21. Consider the pros and cons of such a proposal.
4. How might the socialization of a young child be different when that child grows up in a household in which both sets of grandparents are living in the house as well as the parents? Consider how that child might have differing experiences from a child who grows up in a household with no grandparents present.

Conclusions

Summary

On December 7, 1941, the day Japan launched a surprise attack on Hawaii's Pearl Harbor, 11-year-old Rahn Taoka watched as her Japanese father was arrested in their San Francisco home. He was one of the first Japanese citizens arrested by the U.S. government because it was feared they were spies. The government would soon initiate a nationwide program to round up and incarcerate over 100,000 Japanese Americans and Japanese nationals in the "war hysteria."

Rahn, her sister, and their English mother avoided incarceration, but they had to agree to move to a small town in northern Minnesota where they would stay with their father's European-American business partner. Though Rahn was initially apprehensive, her life in this small town suddenly brightened when she met Marilou. The girls were inseparable and spent endless hours together both in school and out. This friendship transformed Rahn's frightening, strange experience in which she was surrounded by many suspicious peers into a year and a half that she later remembered as one of the happiest times of her life.

When her father was released to Japan in a prisoner exchange, Rahn and the rest of the family went with him, even though his wife and daughters did not speak a word of Japanese. They suffered severe hardships in Japan in the waning days of the war. The daughters were treated as social outcasts by their peers and struggled to adapt to their new cultural community. After many years, they finally managed to move back to the San Francisco Bay Area in 1955.

Finally, 64 years after they had last seen each other, Rahn and Marilou were reunited through the efforts of their children. Within minutes, they were interacting as if they had never been separated. As Rahn reflected, "Don't you find that with any true friend, you can be apart for years and pick up where you left off?" (Lagos, 2007).

What is it about childhood friendships that can make a seemingly impossible situation into one of the best periods of one's life? How do such friendships help protect children when their status in a peer group is of poor quality or when they are making a difficult transition? Some have argued that a special kind of "best friend" relationship in early adolescence is an essential part of healthy development. How might friendships benefit a child, and does having a best friend offer unique benefits? How do friendships change from early childhood through middle childhood and adolescence? Finally, how do girls' friendships and other social relationships differ from those between boys?

Friendships are part of a larger complex of environments outside the home that influence children's development. We can think of the moderate effects of occasional interactions with others as well as the more pronounced effects of sustained relationships, either with friends, enemies, or even with bullies. One other especially influential sustained relationship that emerges in adolescence can be the romantic relationship. Expanding further, we can look at larger peer groups to see how social status relationships work at the level of a clique, a classroom, or a school. Finally, we can consider the broadest cultural communities and their influences on children through the media, especially television, video games, and the Internet.

In Chapter 14, we introduced Bronfrenbrenner's *ecological systems approach* to development as a way of understanding the different social contexts that affect the family. The ecological approach stresses the importance of the environments in which a child develops and the need to consider these environments at several scales, ranging from the family itself, to groups of friends, to the school, to the larger culture. We saw how researchers consider the child's role in each of these "social ecosystems" and how that role interacts with the roles of all other players in those systems. In this chapter, we will see how this approach can be extended beyond the family and consider the kinds of social niches that children occupy in an ever-widening web of social relationships and communities. Socialization processes can occur at each level of grouping, often with quite different patterns of influence, depending on how the child's disposition interacts with her specific niche.

This chapter focuses on these influences of broader groups beyond the family. We will start with the group closest to the family, the friends in the immediate community, and then expand the circle to eventually consider media influences and differences across cultures. Finally, we will consider how gender and other sociocultural roles emerge in these contexts.

Levels of Affiliation

Developmental psychologists have been interested in the influences of peers since the earliest days of psychology (Renshaw, 1981), but research in this area gained significant momentum following two striking findings about the effects of peers on attachment. As described in Chapter 6, both Freud and Dann's (1951) studies of groups of children who relied on one another for support in concentration camps and after their liberation and Harlow's studies of peer-raised monkeys (Meyer et al., 1975; Suomi & Harlow, 1972) showed that peers could alleviate some of the consequences of otherwise dreadful social environments. More recently, the field of evolutionary psychology has stressed that peer relations might be an especially powerful realm of social influence.

The power of peers never ceases to amaze parents. At certain points in development, it certainly seems that peers are more important to children (and especially to adolescents) and more influential than almost anyone else. Some researchers have suggested that, in general, peers are far more influential than parents (Harris, 1998), but most researchers see peers and parents as operating in different spheres of influence. Peers seem especially influential on such things as personal taste, clothing, and hairstyles, while parents hold more sway over such things as career choices and broad social values (Smetana et al., 2006).

To gain a better sense of peer influences, we need to first think about the different ways in which peers might interact. These interactions can be categorized into three distinct levels of affiliation, which apply to other animals as well as to humans: interactions, relationships, and groups (Hinde, 1987, 1997; Rubin et al., 1998). *Interactions* can be prosocial if they facilitate social engagement, antisocial if they discourage social engagement, or withdrawn as in cases of shyness. *Relationships* consist of a progression of interactions over time. Particular relationships then become associated with predominant emotions, such as love or hate, and different degrees of commitment. Finally, *groups* arise from sets of relationships, and they can be evaluated in terms of their cohesiveness, dominance relations, diversity, and local norms. In this system, relationships build on interactions in much the same way that groups build on relationships (Rubin et al., 1998). The developmental study of peer relations involves all levels, but most often focuses on groups.

Q: What are three different levels of affiliation between peers?

The Changing Nature of Social Interactions

Infants' and toddlers' interactions are very simple and not so different from those seen in other animals. They often experience joint arousal (see Figure 15.1). When one child is excited and happy, that state can induce a comparable feeling in another child, which can then cause a positive-feedback loop of increasing arousal. Moreover, sadness and despair in one child can also cause a drop in arousal in the other child, as very young children apparently feel empathy. As seen in Chapter 6, infants and young toddlers are exquisitely sensitive to social agents and the timing of back-and-forth social interactions, such as smiles between mother and child. That sensitivity is only the beginning of an ability to manage smooth, reciprocal interactions with peers.

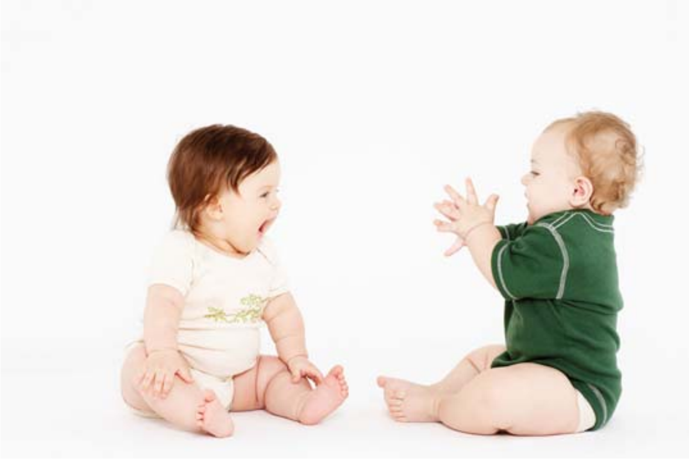

FIGURE 15.1 Early social interactions. Although infants are aware of other social beings, such as other infants, their patterns of interactions may be largely limited to contagion of the emotional states of others.

Preschoolers show considerably richer and more varied repertoires in their interactions than do infants. They show genuine instances of sharing and have some sense of reciprocity, or cooperative exchange. They play pretend games with others, often playacting imagined episodes with each other. Their levels of conflict decrease somewhat with age, and more notably, the kinds of conflicts they experience show developmental changes. In one study, 400 children at ages 2, 3, and 4 years were videotaped as they engaged in routine activities in their preschool classrooms. The experimenters later scored the first conflict episode that occurred during a set observation period (Chen et al., 2001). In most cases, at least one conflict occurred, with several typically occurring at all ages.

What changed with age, however, were several key factors relating to what triggered the conflicts and how they were resolved. The 2-year-olds had more conflicts about the distribution of physical resources, such as vying for a coveted toy (see Figure 15.2). The 3- and 4-year-olds had more conflicts around ideas, such as which superhero is stronger, or around play, such as who gets to be "it" in tag. In addition, the younger children showed less willingness to back down and higher levels of insistence, often prolonging the conflict until an adult intervened, while the older children were better able to resolve conflicts on their own. Dealing with conflict seems to be an essential part of social development from an early age, and children have much to learn to understand what is a reasonable conflict and how to resolve disputes (Chen et al., 2001; Rubin et al., 2003).

Q: How does the nature of conflict interactions tend to change during the preschool years?

FIGURE 15.2 Negative interactions. When 2-year-olds get into fights, they most often fight about toys. When older preschoolers fight, the conflicts are more often around ideas, such as which superhero is stronger, or around games, such as who gets to go first.

In the elementary school years, children experience a huge surge in social interactions. The networks beyond the family, arising from sports teams, the school, and the neighborhood, for example, enable children's social lives to flourish. Peer group sizes increase throughout this period, going from groups of two or three early on to social circles of a dozen or more. During this period, children require less and less adult supervision and can sometimes be found playing in the neighborhood or on school grounds for hours with little or no adult oversight. During this period, most children also shift markedly toward interacting with peers of their own sex. Suddenly, sometimes seemingly inexplicably, girls and boys who have played together for years sort themselves into same-sex groups and engage in predominately single-sex interactions (Fabes et al., 2003; Martin & Fabes, 2001; Strough & Covatto, 2002). According to the psychoanalytic approach to development, this takes place during what is referred to as the **latency period** of middle to late childhood, when sexuality is said to be largely dormant and does not overtly influence interactions. During this period, children also show a decline in pretend play and become more likely to use verbal or physical aggression in conflicts, sometimes with great cruelty. In a similar vein, gossip about others also increases (Crick et al., 2001; Crozier & Dimmock, 1999).

Q: How do patterns of play between the sexes change during early and later childhood, and what classic construct in psychology has been used to explain these changes?

As children enter adolescence, their interactions seem to change yet again. Peer interactions come to predominate over interactions with parents or teachers. Finally, in many cultures, cross-sex interactions emerge as a critical part of most adolescents' social lives. Teenage dating is for many parents one of the most salient and nerve-wracking behaviors of children in this age group.

Developing Relationships

All relationships serve essential functions for the developing child. They serve to transfer information between individuals and help set up stable, enduring patterns of interaction, whether those interactions are between friends and mentors, or bullies and enemies. Relationships can allow individuals to provide mutual support for each other—both social and physical support. In other, more harmful relationships, there may be patterns of dependency and control between individuals. All kinds of relationships, however, can serve to create stable social links, and structured sets of links that are larger than individuals.

Friends With respect to the earliest relationships, infants show unique, repeated interaction patterns with certain individuals, such as with a parent or a sibling, but these interactions are not true friendships. **Friendships** are ongoing, positive reciprocal relationships with chosen companions. As described in Chapter 6, infants have particular expectations of certain specific interactional partners, but these interactions largely lack the reciprocal exchanges (for example, sharing toys or projects) that are essential to friendships. In addition, these relationships develop largely as a matter of convenience, depending on who is accessible, and less because of a desire to be with a specific peer. Some infants are naturally more friendly and outgoing than others and seem to enjoy being around others as opposed to being on their own, but they still do not seem to build structured social connections with others.

Toddlers, on the other hand, develop clear friendships (Howes, 1996; Newcomb & Bagwell, 1995), which seem to consist mostly of animated, positive interactions while playing (Gifford-Smith & Brownell, 2003). Toddlers purposefully choose their friends, usually picking the children most like themselves. They begin to show more prosocial behaviors—for example, sharing and empathy—with friends during this period, but they also begin showing more hostility than before with both friends and enemies.

School-age children develop more sophisticated notions of friendship. For example, they gain a clearer idea of reciprocity, understanding that friends do not just get benefits from each other; they also provide benefits (Hartup, 1999; Selman, 1980, 2003). As their theory of mind skills improve, children start to use their increasing social cognitive capacities to make more elaborate inferences about their friends' mental states and to adjust their behaviors accordingly. In short, they become increasingly adept at putting themselves in their friends' shoes (Rubin et al., 1998). Unfortunately, school-age children also develop some less positive relationship styles, such as bullying and verbal aggression.

Gender differences in friendships become more dramatic with increasing age. By the time they enter elementary school, boys tend to play in larger groups than girls and are more likely to have clear dominance hierarchies within those groups. Girls tend to show more prosocial behavior and empathy in relationships, while boys show more rough-and-tumble play and focus on goals, such as achieving dominance (Hartup, 1996; Rose & Rudolph, 2006). Late school-age children and young adolescents show clear differences in the fragility of friendships. Girls tend to have fewer long-lasting very close friendships than boys and to be more distressed at the thought of losing their friends (Benenson & Christakos, 2003; MacEvoy & Asher, 2012). One possible reason for this gender difference in the length of close friendships may be that girls have more intimate relationships that result in more intense reactions during conflicts, reactions that can cause irrevocable breaks. Greater intimacy may also provide girls with more ability to hurt each other during a conflict, as they may divulge private information that was shared in confidence. Finally, because girls tend to have relationships in the absence of groups, they may not have the benefits of a group to buffer conflict (Rose & Rudolph, 2006). During this period, girls and boys tend to act out against friends in different ways. Girls tend to victimize their friends in social ways, such as conspicuously excluding them from an activity, a form of antagonism known as **relational aggression** (Benenson et al., 2011). In contrast, boys more often victimize friends physically (Crick & Nelson, 2002).

School-age children also tend to try to control their friends' other friends and can become jealous when a close friend develops new, close friendships with others. Although this pattern can exist in older children and adults (Heider, 1958), it is more common in younger adolescents (Parker et al., 2005; Selman, 1980). In early adolescence, jealousy over friends is also more common among girls than among boys (Parker et al., 2005). Friendship jealousy seems to peak in late childhood or early adolescence, which has been explained in two main ways: (1) Younger children may be less sophisticated at engaging in social comparisons, and so they may not consider whether a friend's new close connection implicitly suggests that their friend values them less; older children and young adolescents are generally better at making these social comparisons. (2) Older adolescents may be better able to understand objectively that they cannot meet all of their friend's needs and that other friends can meet different needs without posing a threat to their own relationship (Selman, 1980; Selman & Schultz, 1990). The increase in friendship jealousy in early adolescence may also be related to a proposal made many years ago that a pattern of *chumships* emerges in late childhood in which many children have one favored best friend (Sullivan, 1953; see Figure 15.3). As a former best friend's favored status wanes in early adolescence, jealousy may be more common.

FIGURE 15.3 **Chums.** Harry Stack Sullivan proposed that in late childhood, a special form of close friendship forms in which there is a favored best friend. Sullivan called these best friends "chums."

Q: What are some of the ways boys' and girls' patterns of friendship differ?

As adolescence proceeds, friendships become closer and more intimate, and friends form deeper loyalties (Rubin et al., 1998). Adolescents develop more specific standards about how they expect their friends to behave, coming to expect loyalty, support, and discretion (Furman & Buhrmester, 1992; Johnson, 2003). More generally, they see friendships as entailing high levels of self-disclosure to each other, with corresponding confidentiality. The rise in online communication methods and cell phone texting has provided adolescents with dramatic new ways to communicate confidential information and make self-disclosures to close friends, even when those friends are not physically present. Shy adolescents may be especially prone to using these new methods (Reid & Reid, 2007; Subrahmanyam &

Greenfield, 2008; Underwood et al., 2012). The developmental changes in self-disclosure are often thought to reflect increasingly sophisticated social cognitive skills that enable friends to share more information and build stronger trust with each other (Gifford-Smith & Brownell, 2003; Rubin et al., 1998).

Friendships can provide several advantages to children. They can foster social skills, such as the ability to sense and empathize with the thoughts and feelings of others. Being someone else's preferred companion may also reaffirm a child's sense of self-worth. Friendships can help motivate children to acquire new skills, such as a sport or hobby, and they can help instill in children a sense of their culture's norms (Bukowski, 2001). And it has been repeatedly suggested that friendships can buffer children from life's stresses, whether those stresses arise from moving to a new school or neighborhood or from a family crisis such as divorce (Gifford-Smith & Brownell, 2003; Hartup, 1996; Hartup & Stevens, 1999).

As is often the case, however, causality can be difficult to pin down in studies of friendship effects. Although it certainly seems plausible that friendships directly alleviate the effects of some kinds of stressors, another possibility is that children who have more difficulty forming friendships are also more reactive to stressors. It is obviously unethical to do an experiment in which children are randomly assigned to have friends or to be deprived of them and then subjected to the same kind of stress. Sometimes, however, situations can approximate these conditions, providing more compelling evidence of whether friendships can truly protect children from the effects of stress. For example, if two groups of families with children have to relocate to new, faraway communities, and they are randomly assigned either to neighborhoods with no children or to neighborhoods with many children, the case for causal effects of friendship can be more carefully explored.

Friendships can also have detrimental effects on children, although the positive effects generally far outweigh the negative effects. We have seen that friendships can lead to feelings of jealousy and even aggression toward those who threaten a relationship. In addition, especially among girls, friendships can sometimes foster a tendency toward *co-rumination*, a type of interaction in which friends tend to repeatedly discuss and mull over negative events and emotions in ways that may exacerbate a problem or increase anxiety, despair, and depression (Rose, 2002; Rose et al., 2007; Schwartz-Mette & Rose, 2012). Friendships can also sometimes foster undesirable behaviors. If, for example, a child has some aggressive tendencies, there is evidence that associating with friends who share these tendencies will increase the child's own inclinations toward aggression (Dishion et al., 1995). Finally, the quality of friendships can vary dramatically. Some friendships consist largely of supportive prosocial behaviors, while others involve strong components of envy, rivalry, and bursts of conflict. Those negative interactions can, in some cases, outweigh the positive interactions (Berndt, 1996, 2002; Salvas et al., 2011).

For the most part, however, friendships are a critical, positive aspect of development. They help provide a sense of worth and a set of social skills that can serve as a buffer against a variety of negative experiences. The specific benefits of friendship change with age, but its positive effects persist throughout development, while its few negative aspects pale by comparison.

Imaginary Companions Children may develop relationships with **imaginary companions**—that is, fantasized characters that they make up or objects that they treat as if they were alive. Having an imaginary companion is neither unusual nor a sign of distress in a child. Although popular media have sometimes portrayed children with imaginary companions as deviant or mentally ill, in fact, there are no indications that having imaginary companions is correlated with any sorts of childhood problems. It might seem, for example, that children with imaginary companions are especially lonely or shy, but neither of those conjectures appears to be true (Taylor, 1999). Rather, imaginary companions are a sign of a vivid imagination. And for many years, it has been known that a vivid imagination in a young child is associated with positive outcomes, such as higher levels of creativity (Singer, 1961).

Imaginary companions are quite common, even in children in the elementary and middle school years. In one survey of 1,795 British children between 5 and 12 years of age, 46 percent of the children reported having had an imaginary companion, with a somewhat greater incidence (52 percent versus 48 percent) among girls than boys (Pearson et al., 2001). When children of all ages are considered, some estimates suggest that 65 percent of children have had an imaginary companion at some point (Taylor, 1999; Taylor et al., 2001; see Figure 15.4).

Imaginary companions may enable many young children to try out their developing ability to have social relations outside of the family. One reason that researchers talk about imaginary "companions" as opposed to just imaginary "friends" is that imaginary companions can fill very different social roles for children. In addition to being playmates, they may be older mentors, babies to care for, or animals, among others. In many cases, they may be invisible; in other cases, they may be partially embodied in a doll or stuffed animal (Taylor et al., 2001). This rich variety of social roles can be useful to children as they experiment with different forms of relationships. Imaginary companions can therefore provide the child with an opportunity to safely enter a world with a wide range of social possibilities, in which the child can try out many forms of social interactions different from those she typically experiences.

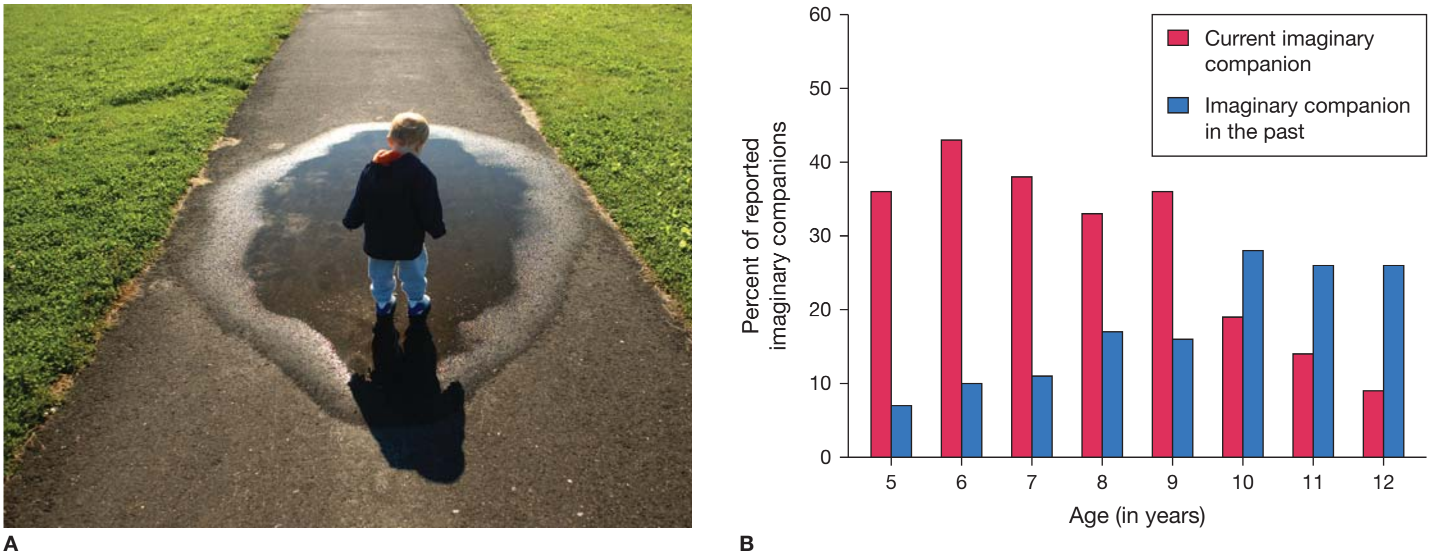

FIGURE 15.4 Imaginary companions. (A) Imaginary companions are quite common, not only in elementary school but even in middle school. When the entire span of childhood is taken into account, the majority of children report having had an imaginary companion sometime during that period. **(B)** The graph shows how the incidence of having an imaginary companion changes with age. In this study, over 50 percent of children at certain ages reported either having an imaginary companion or having had an imaginary companion. Older children either forgot having had an imaginary companion earlier or chose not to disclose that fact. Adapted from Pearson et al. (2001).

Imaginary companions also serve several other purposes for children. They may allow the child to act out various social scenarios in a nonthreatening manner, they may alleviate loneliness or boredom that occasionally afflicts virtually all children, and they may allow children to deal with frightening situations or work out problems. In almost all cases, however, children do realize that their imaginary companions are not real (Taylor, 1999). They may attribute to their imaginary companion a personality, as well as beliefs, desires, and other emotions, but they do all of this with full knowledge that their imaginary companion is not really "there" in the sense that other people are.

Children with imaginary companions tend to have somewhat higher levels of some cognitive and social skills. They tend to be less shy and are more able to consider situations from another's point of view, a valuable skill in many social situations (Taylor, 1999; Taylor et al., 2004). Sometimes, the imaginary companion can be a vehicle for a child to tell his parent about a problem he is encountering. For example, a child might tell a parent that his imaginary companion is being picked on at school as a way of relating his own experience. (This practice is not so different from the adult technique of broaching an awkward topic by saying, "I have a friend who [has the following problem].") An imaginary companion also enables a relatively helpless child to feel more powerful or competent as he acts out roles with his companion that might not yet be feasible in daily life. More generally, imaginary companions increase social skills and social understanding (Taylor et al., 2004) and provide a better sense of self-knowledge (Davis et al., 2011). They also have been shown to increase children's referential communication skills—that is, the ability to direct others' attention to objects or tasks (Roby & Kidd, 2008). Thus, children with imaginary companions tend to show more advanced communication skills in experimental tasks in which they have to communicate to someone behind a screen how to identify the correct picture from a set. (They are not better at understanding instructions in these tasks, just at giving them.)

Why do imaginary companions disappear as the child grows older? One likely reason is that, as the child experiences a wider range of real relationships, the imaginary ones become less necessary. Many cultures also stigmatize adults with imaginary companions, and children may choose to censor their own imaginations as they become aware of this stigma. It is interesting to note that imaginary companions become much more acceptable for adults when they are in extreme isolation. Consider, for example, the main character in the 2000 film *Cast Away*, who is marooned on a desert island and develops an imaginary friendship with a volleyball. The ball acquires a distinct character that is deeply missed when it is lost at sea. It is easy to empathize with the need for a companion in times of isolation, suggesting that, even as adults, we retain vestiges of the cognitive and emotional roots that give rise to children's imaginary companions.

Bully-Victim Relationships Some relationships have decidedly negative consequences for one or both of the individuals involved. One especially vivid and much-studied case involves relations between bullies and victims of bullying. **Bullying**, which is also known as **peer victimization**, generally consists of making verbal or physical threats or attacks against a victim. This form of aggression is repeated and sustained over time and is typically directed against a victim who is unable to defend himself (Espelage & Swearer, 2003; Olweus, 1993). Most of the time, it occurs when others are watching. These characteristic bullying patterns of intimidation and aggression are extremely common and consistent across cultures (Olweus, 1993; Pepler & Craig, 1999).

Bullying is widely recognized as one of the major problems in schools (Sharp & Smith, 1994). Victims of bullying often find it extremely painful, and when it occurs at school it can contribute significantly to not wanting to attend school or to a very negative attitude toward school. Bullied children are often unhappy, depressed, and lonely. As always, the direction of causality can be difficult to ascertain. Depressed, unhappy, and lonely children may be more prone to being bullied, but many think that being bullied contributes to these states. One chilling recent finding was that 60 percent of 41 children who engaged in shooting sprees in schools were reported by neighbors, friends, and teachers as having been victims of bullying (Vossekuil et al., 2002). This is far higher than the typical rate of roughly 10 percent of children having been bullied (Kumpulainen et al., 1999).

Do bullies and victims have characteristics that make it possible to predict who will bully and who will be victimized? In each case, some common tendencies have been repeatedly reported. The most central characteristic of victims seems to be conveying the impression that they will not answer aggression with retaliation (see Figure 15.5). The victim may be physically smaller or weaker, but in some cases, behavioral clues can indicate a victim's docility or submissiveness, even if the individual is physically quite large. In short, what seems to matter most is that the victim appears to be a safe target to aggress against (Olweus, 1997). Victims frequently do not have popular or powerful friends, apparently reinforcing the sense that aggression against them will not provoke a response from anyone who could pose a threat. In addition, victims often tend to interpret provocative behaviors, such as teasing, as more aggressive than they actually are, thus indicating to bullies that they are liable to respond with fear and psychological pain (Sullivan, 2000).

FIGURE 15.5 **Bullying.** The effects of bullying can be highly negative in the long run for both victims and bullies.

In other respects, however, victims can be quite a diverse group. While some are timid, withdrawn, and nonaggressive, others are extroverted and even aggressive (Olweus, 1997; Sullivan, 2000). If the extroverted, aggressive child is nonetheless seen as weak and unable to retaliate effectively against violence, that child may still be victimized. Victims also tend to show high levels of anxiety around bullies, which seems to fuel the bully's aggression. In a sense, this picture of victims leaves room for optimism for reducing bullying, because victims' behaviors, which are potentially changeable, seem to be more important triggers of bullying than more permanent physical traits.

Bullies also have a number of distinguishing characteristics. Bullies are not generally individuals of low self-esteem who are compensating for their feelings of inferiority by dominating others. Although this is a popular way of characterizing bullies, there is little evidence to support it (Batsche & Knoff, 1994; Baumeister et al., 1996; Olweus, 1993). In fact, inflated self-esteem may facilitate and empower bullies. Bullies often have siblings who engage in bullying or even parents who sometimes bully others. These correlations could result both from children modeling the behaviors of these family members and from their shared, genetically rooted dispositions. Bullies usually do not choose their victims out of **reactive aggression**, which would involve retaliating for an offense the victim committed against them. Instead, they tend to act out of **proactive aggression**, abusing the victim because it helps them achieve a goal, perhaps taking something the victim owns or simply making the victim miserable (Dodge, 1991).

Q: Describe three distinct forms of aggression shown by children, and characterize how they might vary across the sexes and across bullies and nonbullies.

Bullying tends to be most prevalent early in adolescence, during middle school, and tends to decline in high school (Pellegrini & Long, 2002). The reasons for this decline are unclear, but one factor may be peers' increasing intolerance of bullying and the social ostracism of those seen as aggressors. Bullies seem to be angrier than other children, having higher sustained levels of anger and being more prone to temper flare-ups (Espelage & Swearer, 2003). They are also more likely to have criminal convictions later in life (Olweus, 2011). One popular view of bullies is that they have certain deficits in processing social information that lead them to make incorrect attributions about others (Crick & Dodge, 1994). Specifically, they are thought to have deficient theories of mind that lead them to make more hostile attributions about the actions of others than are warranted. This view, however, does not fit those cases in which a bully has a precise awareness of the victim's mental state and uses it to maximally humiliate or antagonize the victim (Sutton et al., 1999a, 1999b).

There are three main types of interventions to curb bullying: (1) regulating the bully's behavior through external means, such as punishment; (2) having the bully regulate his own behavior internally; and (3) changing the victim's behavior. It is quite clear that external regulation of bullies works. If teachers or other adults closely monitor bullying and punish it, it will decrease (Ttofi & Farrington, 2011). It is also possible to improve a bully's empathy and make him feel more uncomfortable mistreating others (Olweus, 1993, 1994). One way to increase empathy might be to get a bully to imagine the situation from the victim's viewpoint or to think through the consequences of bullying (Caravita et al., 2009; Cirillo et al., 1998)—but these internal changes are less effective than external ones. They do not bring about as much of an immediate cessation of bullying. Some researchers suggest that bullies do not have a general problem feeling empathy; they just do not feel it when they initially engage in bullying in a particular instance (Espelage & Swearer, 2003). Overall, despite many studies of interventions designed to reduce bullying by increasing the aggressors' social skills, such as their empathy and perspective-taking, these programs have been, at best, only modestly effective (Vreeman & Carroll, 2007).

Less research has focused on techniques for changing the victim's behavior, which is unfortunate, since this behavior can easily make the individual vulnerable in new situations. Training in assertiveness and self-confidence sometimes helps victims (Sharp, 1996), but it is challenging to convince anxious, fearful children to stand up for themselves in a manner bullies will find convincing. This is an important area of future research, as the child who gives off certain signals, such as high social anxiety, will be detected by bullies in many situations, and adults will not always be around to punish tormentors at the mall, at summer camp, or at the movie theater.

Research on bullying illustrates how dynamic interaction patterns can become self-perpetuating and more intense over time. It also illustrates the challenge of intervening, given the interconnected set of factors that contribute to and sustain bullying. A clear goal of future research is to identify the most effective points in such interactive patterns in which to engage in interventions. The group contributions to such effects will be more apparent when we consider the group level of affiliation.

Enemies Some negative relationships go in both directions, which is the case when two children become enemies, either after a friendship ends or in a relationship that is negative from the start. The pattern of **mutual antipathies**, in which two children intensely dislike each other, can occur between bullies and victims (Card & Hodges, 2007), but it can also occur between two children who are each aggressive and dominant (Abecassis, 2003; Abecassis et al., 2001). In contrast to bully-victim relationships, **inimical relationships** are more symmetrical, in that the children are equally hostile and aggressive toward each other and consider each to be the other's enemy (Card, 2007). Interestingly, preschoolers very rarely have enemies, with incidences usually under 2 percent (Abecassis, 2003; Card & Hodges, 2007). Starting in elementary school, however, far more children have enemies—well over 30 percent according to one study (Abecassis et al., 2001). And in later childhood, there is a marked increase in enemy relationships (Berger et al., 2011; Hodges & Card, 2003). These relationships often cause both parties to avoid each other, but in some cases they are both drawn into a cycle of mutual aggression and retaliation in which revenge becomes a kind of social bond. Having enemies is stressful, and children with enemies can show many of the same symptoms as victims of bullying (Abecassis, 2003; Abecassis et al., 2001; Card & Hodges, 2007).

Aggression between enemies usually takes one of two forms. Boys, especially at early ages, engage in more physical aggression, while girls tend to show more relational aggression (see Figure 15.6). This latter type of hostility involves efforts to damage an individual's social relationships through rumors, gossip, and ridicule, potentially causing the person to be excluded from a desired peer group (Crick & Nelson, 2002). Some researchers have found gender differences in physical aggression but equal incidences of relational aggression among girls and boys (Espelage et al., 2003). Antipathy also often seems to arise between members of groups representing different interests and backgrounds, such as between students who receive very high grades and those who are more focused on sports. There certainly can be mutually aggressive relationships between members of the same group, but more often it may be that "opposites detract" (Laursen et al., 2010).

In short, mutually aggressive relationships are stressful and related to a wide range of negative developmental outcomes in terms of children's social adjustment, depression, and more general acting out and misbehavior. Again, however, the direction of causality is unclear. Perhaps the same personality factors that make a child more prone to

FIGURE 15.6 **Relational aggression.** Relational aggression can cause great discomfort in others through gossip or rumor, with effects that can be just as devastating as those from physical aggression.

mutually aggressive relationships also lead to other social difficulties.

Dating and Romantic Relationships As children enter adolescence, a new form of relationship becomes more and more common: romantic relationships between pairs of individuals. We will define **romantic relationships** as mutually recognized voluntary interactions that are seen as more intense than other relationships. These relationships are also distinguished by displays of affection, either with actual sexual behavior or with the anticipation of such behavior occurring (Collins et al., 2009). As seen in Figure 15.7, the rate of romantic relationships doubles from age 13 to age 17, from an incidence of 36 percent in 13-year-olds to 54 percent in 15-year-olds to 70 percent in 17-year-olds (Collins et al., 2009). It was commonly thought that such a rise was closely linked to the maturation of sexual gonads and sex-related hormones such as testosterone and estrogen, but closer analysis tends to show that the rise is more closely related to age norms for dating in various cultures (Carver et al., 2003; Collins et al., 2009; Dornbusch et al., 1981). Similar age-related norms seem to be found in both different-sex and same-sex relationships, with somewhat later rates of incidence for same-sex relationships, perhaps because such relationships are not endorsed by many cultures (Floyd & Stein, 2002). In adolescence, girls are somewhat more likely to have both boys and girls as partners or as potential partners than do boys (Collins et al., 2009).

Sexual orientation tends to remain quite stable across adolescence and young adulthood among those who initially identify themselves as primarily preferring different-sex or same-sex partners (Savin-Williams et al., 2012). Those who identify themselves as bisexual tend to show more change, with women showing a shift to mostly heterosexual relationships and men more equally distributing themselves among the categories of bisexual, homosexual, and heterosexual relationships. Individuals who are involved primarily in homosexual or bisexual romantic patterns unfortunately often suffer from stigma, prejudice, and discrimination from others who disapprove of same-sex relationships. It is particularly tragic that the more stigma and prejudice a same-sex couple experiences, the more likely it is that their own relationship quality will be negatively affected. Fortunately, at least some same-sex couples are able to shield, and sometimes even strengthen, their relationships in the face of such prejudice. Researchers are trying to better understand the strategies that more successful couples use to respond to stigma and prejudice (Frost, 2011).

Compared with other kinds of relationships with peers, adolescent romantic relationships tend to have more conflicts. This may seem surprising, given that those relationships are more intimate, but they are also more intense and are typically of relatively short duration (about 18 months or less), with the breakups often laced with conflict. Sexual relationships are seen by girls as more appropriately occurring in romantic relationships than in more casual relationships, a perception that is not as strong among boys (Collins et al., 2009). As seen from the perspective of evolutionary psychology, this difference in perception follows from the argument that men seek diverse mates to maximize procreation, whereas women seek mates who will show longer-term loyalty during pregnancy and child rearing (Buss & Shackelford, 2008).

What factors predict which pairs of individuals tend to form romantic relationships? With heterosexual adolescent couples, males tend to choose same-age partners where possible and females often choose somewhat older males. Despite some claims that opposites attract, adolescents generally choose partners who are similar to themselves in level of physical attractiveness, popularity, and even mood—for example, a depressive orientation (Collins et al., 2009).

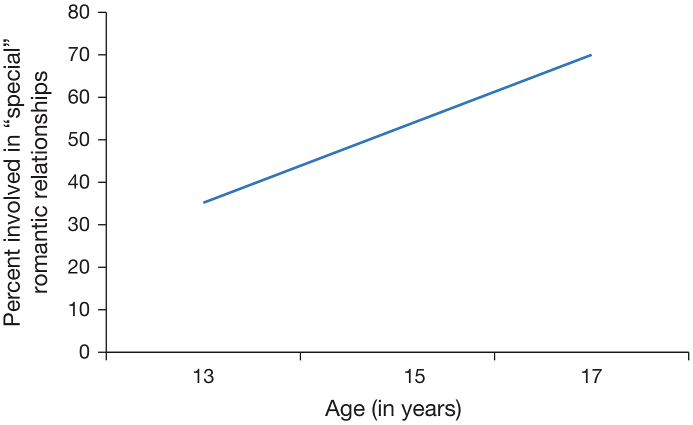

FIGURE 15.7 **Rise in romantic relationships among teenagers.** The incidence of romantic relationships reported as "special" doubles between ages 13 and 17. Adapted from Collins et al. (2009).

Developmentally, romantic relationships have often been described as shifting in their nature over the course of adolescence. Older adolescents tend to see their significant others as more supportive, close, and interdependent. The shift seems to be most dramatic between ages 15 and 17 years (Collins, 2003). During that period, the rate of dating goes up from roughly 25 percent to 75 percent. The length of relationships also increases, with those younger than 15 rarely having relationships lasting more than 11 months and the majority of those older than 17 having relationships that last longer than 11 months. Younger adolescents tend to choose partners for reasons that are often superficial, including clothing style and standing of the potential partner in a peer network. But fortunately, older adolescents tend to focus on partner traits that are more related to fostering intimate relationships and longer-term compatibility. Older adolescents are also more likely to resolve conflicts through compromise. In short, it appears that the ability to form romantic relationships is a skill that develops over the course of adolescence into a more durable and rewarding form.

Researchers argue that adolescent romantic relationships and dating are important because the developmental trajectory of such relationships is related to the quality of relationships later in life (Collins et al., 2009; Simpson et al., 2011). Difficult romantic relationships in adolescence have been linked to difficulties in later romantic experiences (Grello et al., 2003). Moreover, simply having romantic relationships may increase the risk of experiencing later depressions, given that a breakup of those early relationships is likely. Overall, however, adolescents who shift to deeper, more meaningful relationships as they progress through adolescence seem to have a better chance of having sustainable rewarding relationships as young adults. One revealing line of work suggests that it is not just conflicts themselves that matter to long-term relationship quality, but how couples recover from such conflicts. Thus, couples who recover from conflicts well in adolescence are more likely to later have more stable, positive relationships that provide greater satisfaction to both members of the relationship (Salvatore et al., 2011).

Social Groups

Infants and young toddlers do not form groups of their own making, probably because they lack the cognitive complexity needed to manage a group. Preschoolers do form groups, but they are often temporary, forming briefly around a particular activity and then dissolving. Preschool girls tend to play in smaller groups of the same sex, and in those groups they tend to be cooperative, engage in conversation, and show concerns about relationships. Preschool boys tend to play in larger groups of the same sex, and in those groups they tend to compete, engage in more physical roughhouse play, and show concerns about dominance relations (Maccoby, 1998; Parker et al., 2006).

Dominance hierarchies start to appear between group members, and these networks of social status relationships resemble those of many other species (see Chapter 13). These hierarchies can reduce aggression within groups, as subordinate members tend to reserve aggression for those of even lower status, and dominant members only rarely have to show aggression to assert their higher position (Sluckin & Smith, 1977). One interesting aspect of preschoolers' dominance hierarchies is that even though such hierarchies can be quite stable over time, the children are usually not consciously aware of their own status in the hierarchy (Strayer & Santos, 1996). The mental mechanisms that maintain the social structure appear to be largely implicit. This finding may sound improbable, but in fact, we have seen very similar cognitive patterns in young children in other domains. Just as young children are unaware of some properties of their language or their memory, even though they use them both heavily, they show little awareness of their own social position within a group, even as they honor that position in their behavior.

Cliques and Crowds Among elementary school children, groups have a very different character. Much more stable **cliques**, which are small groups of peers who voluntarily spend a great deal of time together and seem to actively exclude others, start to emerge (see Figure 15.8). Cliques play an important role by providing the child with a sense of belonging as well as helping form a group identity. Being popular becomes a powerful social goal of many children. By this time, children can be acutely, and often painfully, aware of their own status within groups, knowing full well when they are unpopular or viewed as outsiders. Being rejected by peers and not included in a group is linked to problems of psychological adjustment (Ladd, 2006), but it can be difficult to tell if rejection causes such problems or if children with such problems tend to be rejected, or both.

In a related vein, children in this age group show a marked increase in **social comparison**, evaluating others relative to themselves or their group, such as assessing who is smarter, richer, more athletic, or better looking. Even preschoolers engage in some social comparison (Butler, 1998; Rhodes & Brickman, 2008; Yee & Brown, 1992), but it becomes much more frequent and intense during the later elementary school years. Presumably, during this time, children become more sophisticated at noticing and interpreting differences between their own group and other groups—for example, becoming aware of social rules that might be special to a group. One consequence of these group comparisons is that children tend to evaluate their own group more positively and other groups more negatively, even when group assignments are random (Bigler et al., 1997). With respect to majority and minority

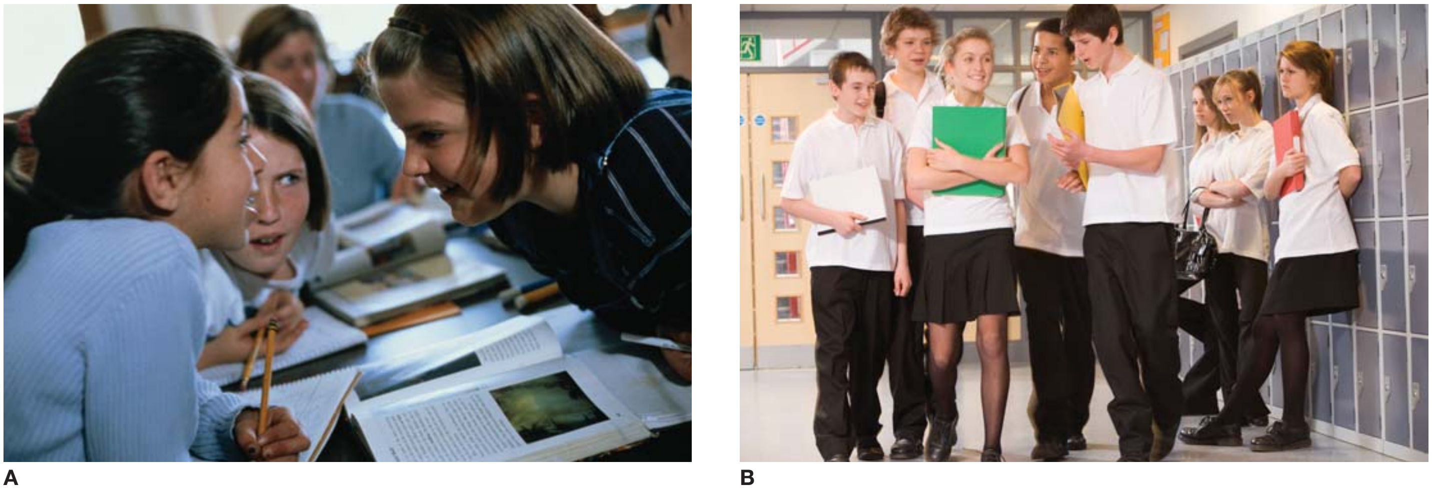

FIGURE 15.8 Social groups in early adolescence. (A) Cliques appear in middle childhood and reach their peak in the early teens, declining in high school. **(B)** In a group of children such as these, often the most popular children are the most physically attractive.

groups, there are indications that children as young as 7 years old reflect the adult pattern of showing stronger out-group biases when they are members of a majority group as opposed to a minority group (Newheiser & Olson, 2012).

Q: When, in the course of development, do cliques tend to first appear? Why might they not appear until that age?

Finally, in adolescence, cliques start to decline in importance. Although some adolescents still try to maintain cliques and reap the benefits of belonging to an exclusive group, most adolescents are less focused on cliques (Adler & Adler, 1998). The makeup of social groups also changes, shifting toward more mixed-sex groups in which both sexes interact and collaborate. There is also a rise in what are sometimes called "crowds" in adolescence, where stereotyped identities, values, and activities tend to define a particular crowd and where a particular adolescent might get a reputation (perhaps not fairly) that links him to one crowd. Thus, in high school, it is common to talk of groups such as nerds, jocks, Goths, stoners, punks, and preppies. For many high schoolers, affiliations with such crowds can have enormous influences on their friendships and daily activities (Brown & Klute, 2003).

Any careful observer of children at different ages would notice many of these patterns. The more challenging research questions center around the different ways that children come to occupy specific niches or social roles within groups. As we examine the wide variety of social roles that children occupy in groups, we will also keep in mind questions about how developmental change interacts with the different social roles children play in their peer groups and with the broader social patterns in these groups. To do this, we will consider a wide range of research that measures children's social status in groups. Many of these studies investigate the factors that lead children to hold certain social positions and what the developmental consequences might be of occupying these positions.

Sociometric Status and Social Interaction For more than 75 years, researchers have been interested in devising a typology that describes how peers interact with each other, which could then be used to classify children into different kinds of roles within groups. In 1934, the psychiatrist Jacob L. Moreno developed a method of discussing social status in groups known as *sociometry.* Moreno believed that analyzing a group's internal structures and the particular position that an individual occupies in these structures—that is, the person's **sociometric status—**could help predict the person's psychological well-being (Moreno, 1951). Moreno determined sociometric status based on how much peers liked or disliked others in their group. Moreno's sociometric method has become a common tool for understanding children's development within the context of social groups. Over the years, a typology of five types of children has developed: *popular children*, *rejected children*, *controversial children*, *average children*, and *neglected children* (Newcomb et al., 1993).

The most common sociometric method for determining sociometric status and sorting a group of children into these five types is the **peer nomination** technique. Each child in the group is individually asked to name the children in the group whom they like the most and those they would most like to play with (Coie et al., 1982). They are also asked to nominate the children whom they like the least and those they would least like to play with. Computing the "like" and "dislike" ratings enables researchers to create the five status types, which have proved to be associated with different behaviors and kinds of abilities.

Popularity is a topic of great concern to older children and teenagers and is frequently talked about (Adler & Adler, 1998). In sociometrics, **popular children** are nominated as being liked by most children and disliked by few children, often as a result of both appealing physical attributes and social skills. For example, popular children may be liked by other children because they are often smiling or because they are friendly, helpful, and sensitive to others. But well-liked children are not necessarily the same children as those who are perceived as popular by their peers. Perceived popularity (which is not always the same as true popularity) is more influenced by perceived power and dominance within a group than by factors such as kindness and trustworthiness (Parkhurst & Hopmeyer, 1998).

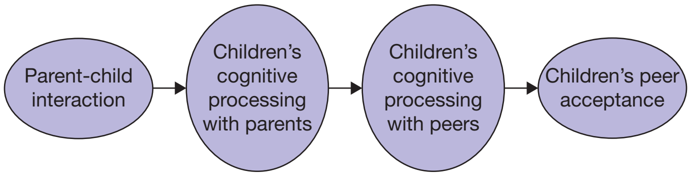
Physical attractiveness is one attribute that is often related to popularity (Berscheid & Walster, 1974; see Figure 15.8B). Even preschoolers who are rated as more physically attractive are more likely to be popular among their peers (Vaughn & Langlois, 1983). Later on, near puberty, early physical maturation is related to popularity. Moreover, as seen in Chapter 3, even in infancy there seems to be considerable consensus on what makes someone attractive. Thus, some children would seem to have, simply by accident of birth, a better chance than others at being popular. (There is a large literature also suggesting that physically attractive people continue to enjoy a number of advantages in both their private and professional lives; see Berscheid & Walster, 1974; Snyder et al., 1988). At the same time, physical attractiveness is not a completely fixed attribute. A child's attractiveness can vary considerably as a function of demeanor, hair and clothing style, and mood. Besides physical attractiveness, athletic ability and performance may also be physical factors that contribute to a child's popularity. But athletic performance tends to be more associated with popularity in boys than in girls (Closson, 2009; Lease et al., 2002a, 2002b).

Beyond physical attributes, many psychological attributes are correlated with popularity and unpopularity. There seem to be different sets of attributes that make children popular to different sets of peers. One study with 452 grade school boys (fourth to sixth grades) found two quite distinct types of children that were highly popular within their respective peer groups (Rodkin et al., 2000): popular prosocial "model" children and popular antisocial "tough" children. The model children were athletic, adept at leadership, cooperative rather than competitive, studious, outgoing, "cool," and nonaggressive. Moreover, kindness was also a common trait in model children (Estell et al., 2003; LaFontana & Cillessen, 2002). The tough children were "cool," athletic, aggressive, and generally antisocial toward authorities and social norms. These traits were noticed not just by independent observers but also by peers. Both groups of popular children were "cool," which seems to reflect a kind of social adroitness and awareness, but beyond that trait, they displayed sharply contrasting types of personalities. This contrast has been found in other studies with both boys and girls. The causal relation is not always obvious, however. A behavior may make a child popular, but it is also possible that being popular may help cause certain behaviors to emerge.

The social adroitness of popular children has been examined more systematically in studies of the social cognitive capacities of popular children. One review of the sociometric literature concluded that popular children are more adept at navigating a wide range of social situations, including perceiving actors' intentions, developing social problem-solving strategies, and focusing on interpersonal relations—that is, how to get along with other children or adults—in addition to attaining concrete instrumental goals, such as obtaining a desired object or mastering a task (Gifford-Smith & Brownell, 2003). The connection between social cognitive skills and peer acceptance may appear quite early, with some studies showing associations between higher theory of mind and peer acceptance in preschoolers (Slaughter et al., 2002).

One facet of popularity occurs in the cliques that appear in late childhood, usually around the sixth grade, and that continue into early adolescence, usually starting to decline after the eighth grade (Crockett et al., 1984). These small, exclusive peer groups can cause pain for those who are excluded, as well as sometimes causing anxiety for group members concerned about maintaining their status. It is interesting that cliques are rarely stable beyond a few months (Adler & Adler, 1995). They are frequently forming and dissolving or adding and dropping members, so that the composition can vary dramatically over time. Cliques may be especially sought out during the middle school years because children see them as a way to catapult themselves into an elite status group (Schrum & Cheek, 1987). As children grow older, they may start to realize that membership in such transient groups does not really confer lasting positive status and that members of cliques can also be targets of considerable resentment and distrust, especially by former friends who have now been excluded by a child who has recently joined a clique (Adler & Adler, 1995). They may also start to realize that they themselves may likely be dropped from a clique and accountable to former friends that they excluded upon joining the clique.

There is a huge literature on a group of children known as **rejected children**. These children receive the highest number of nominations as peers who are most disliked. When this group is studied more directly, these children seem much more likely than other children to interpret ambiguous actions by others as hostile (Dodge et al., 2003).



Parent-child interaction
Children's cognitive processing with parents
Children's cognitive processing with peers
Children's peer acceptance

FIGURE 15.9 A causal model of peer acceptance. Several researchers have suggested that specific parent-child interaction patterns help instill certain social cognitive processing skills in children that then influence social cognitive processing of interactions with peers, which in turn influences peer acceptance. In practice, it is difficult to tell if such links are causal as opposed to correlational, mediated by other variables. Adapted from Rah & Parke (2008).

This pattern of thought in rejected children is often known as the **hostile attribution bias** (Nasby et al., 1979).

How might something like a hostile attribution bias appear in development? Some scholars have argued that certain kinds of social cognitive styles emerge out of parent-child interaction patterns and then come to influence peer interactions (Rah & Parke, 2008). This kind of model is shown in Figure 15.9. In particular, these researchers believe that parents' manner of interaction with their children can lead to changes in three kinds of social cognitions in children: goals, strategies, and attributions (Crick & Dodge, 1994). Thus, if a parent is constantly berating and coercing a child, that child might focus on instrumental goals—for example, obtaining a good grade—rather than relational goals—for example, developing a better relationship with the parent. Instrumental goals might in turn lead to strategies that neglect the parents' feelings and interests, which in turn could lead to attributions about the hostile intent of the parents. The social cognitions that are learned from parent-child interactions are then transferred to interactions with peers, with the child now continuing to make hostile attributions about ambiguous situations, attributions that often lead to peer rejection.

There are many studies suggesting associations between parent-child interaction patterns and certain kinds of cognitive styles, as well as many studies showing associations between children's social cognitions and peer acceptance or rejection (Crick & Dodge, 1994; Dodge et al., 2003). Certain longitudinal studies suggest that the patterns of correlation point toward the causal model shown in Figure 15.9, in which parental behavior ultimately causes patterns of peer acceptance or rejection (Rah & Parke, 2008). But because these studies are not experimental in nature, it is still possible that the patterns of association do not indicate causal relationships. For example, children and their parents might share common genotypes that might predispose them toward more hostile attributional styles, which in turn might influence interactions between the children and their parents and between the children and their peers. Similarly, growing up in a harsh and threatening environment may increase hostile attributional styles in both parents and children, which in turn may carry over and contaminate relations with peers. Longitudinal designs are meant to be able to tease apart such alternatives, but in practice it is difficult to make a definitive conclusion.

As researchers examine popularity in more subtle and detailed ways, they start to see how particular kinds of interactions might relate over time to particular kinds of aggression. For example, among children from ages 10 to 14, especially girls, relational aggression predicts, and seems to cause, a form of "perceived popularity," in which a child is seen as one of the most popular; but this perceived popularity does not seem to lead to "sociometric popularity," in which the child is the one whom children most want to have as their friend (Cillessen & Mayeux, 2004; Cillessen & Rose, 2005). Sadly, this causal link between relational aggression and perceived popularity may provide an incentive for some children to gossip and slander others.

When peer group acceptance is explained in terms of social cognitive capacities, this is known as the **social information processing** approach (Crick & Dodge, 1994). This approach is often broken up into five steps (see Figure 15.10): (1) The child must encode social cues and the setting in which they occur (for example, *Joe bumped into me in a crowded hallway*). (2) The child must make sense—that is, interpret the cause and intent—of the cues in that situation (for example, *Joe bumped into me because he is out to get me*). (3) The child must set up goals for responding to the situation (for example, *I have to figure out a way to retaliate against Joe*). (4) The child must access a set of possible responses to attain that goal (for example, *I could go up and bump into Joe right away, or I could*

2. Interpreting cues
1. Encoding cues

FIGURE 15.10 Social information processing model of attributions in children. Crick and Dodge (1994) proposed that the child processes social information in five steps that lead to a final behavioral response. In the model shown here, the process is seen as a repeating cycle that can lead a child to have a hostile attributional style and to be a rejected child or to have a more positive attributional style and be a popular child. Adapted from Crick & Dodge (1994).

spill food on him in the cafeteria). (5) Finally, the child must decide which of the possible responses is the best one to use.

Rejected children seem to have deficits in every one of these five steps (Crick & Dodge, 1994), although most research has focused on the second step, in which the child constructs an interpretation of the cues. Studies repeatedly find that rejected children tend to be both aggressive and more inclined to make hostile attributions about the actions of others (Orobio de Castro et al., 2002). At the same time, rejected children do not automatically make a hostile attribution about an ambiguous event. If a rejected child feels positively toward a peer, the same ambiguous action is much less likely to result in a hostile attribution than when it is carried out by a peer for whom the child has negative feelings (Peets et al., 2008). Thus, the hostile attribution bias is strengthened by the extent to which a child feels a general dislike for another child. Since many rejected children have at least some friends (Cairns et al., 1988), they show quite different attributional patterns when settings include primarily their friends as opposed to other groups of peers for whom they have either neutral or negative feelings. The finding of increased deficits in all five steps means that rejected children may initially make mistakes in encoding critical features of an event, as well as generating a nonoptimal set of response strategies and then choosing an option that is especially aggressive and usually counterproductive.

Rejected children tend to have difficulties in adjustment in childhood and adolescence, with higher rates of emotional problems (for example, anxiety and depression) and behavioral problems (for example, being disruptive in class, getting into fights, and substance abuse; Bierman, 2004; Rubin et al., 2005). There are also indications that children who exhibit high levels of demanding behaviors at a younger age are more likely to become rejected children in later childhood (Dodge et al., 2003). Unfortunately, when a child is classified strongly as being in the rejected group, that classification can remain quite stable over much of childhood and adolescence (Rubin et al., 2005).

Yet, aggression does not always lead to rejection. Roughly half the children who are seen as aggressive are not rejected by their peers (Coie et al., 1991). It appears that children who respond to an unambiguously aggressive action in an aggressive way are not as likely to be rejected as those who use aggression to achieve a particular goal. In other words, if aggression seems to be a reasonable response to a clear provocation, other children do not seem to take that behavior as a basis for rejection.

Children who are classified as controversial score high on both the like and the dislike scales. In many ways, they are the opposite of the neglected children (discussed shortly), as they are noticed by everyone, just in different ways. **Controversial children** are seen as sociable and as leaders, but they are also more likely to be seen as aggressive and arrogant, with boys showing more of a propensity for aggression and girls for arrogance (Gifford-Smith & Brownell, 2003). Controversial children do not seem to have negative developmental outcomes. In addition, the classification of being a controversial child shows less stability over time than being either a rejected child or a popular child. Moreover, during adolescence, controversial children may become more popular with peers who value a certain degree of rebelliousness (Gifford-Smith & Brownell, 2003).

Children who have average values on the like and dislike scales have not been studied much in their own right because they are generally assumed to have unremarkable behaviors and psychological problems. They may also be quite mobile in that they can move in and out of the popular groups. There is no evidence that average children fare any worse than popular children in the long run.

Neglected children seem to be largely ignored by their peer group and do not appear to be high on either the like or dislike scale. These children go through their days without much notice, and they do not seem to fare much worse than average children (Asher & Wheeler, 1985; Gifford-Smith & Brownell, 2003). Neglected children seem to be just as happy and no more lonely than peers who are classified as average. They do seem to be more shy and withdrawn (Coie & Dodge, 1988), but this behavior does not seem to be associated with any negative outcomes. There is also some evidence that being in the neglected category is less stable than categories such as rejected and popular, suggesting that neglected children might move in and out of other categories, such as average and popular, at different times in development (Gifford-Smith & Brownell, 2003; Newcomb et al., 1993).

Overall, the sociometric method has been useful for classifying relationship patterns among peers. The classifications with the most stability over time, rejected and popular, are also the most divergent in terms of developmental outcomes. Children who are well liked and not disliked tend to have happy lives with relatively low anxiety and relatively few behavioral problems. Children who are strongly disliked and not liked tend to have unhappy lives tainted with depression, anxiety, and a large number of behavioral problems. Children who are labeled as neglected, controversial, or average do not seem to have any obvious problems. It is tempting to draw causal inferences here, but a more cautious interpretation is more appropriate. It may be that certain attribution patterns cause peer rejection or acceptance, but it may also be that peer rejection or acceptance greatly amplifies a particular attributional style. In addition, it may be that other variables, such as a difficult home life, may causally influence both attributional styles and attitudes of peers. In reality, it seems likely that all these factors, among many others, interact in a complex web of cycles and feedback loops, making any simple causal chain implausible.

Longitudinal studies are now also revealing that peer relations can have effects on quite subtle social cognitions, which in turn can feed back on social interaction abilities. For example, difficulty understanding faux pas—social blunders such as violating a local culture's rules of etiquette—can be linked to peer rejection over time. In younger children (5 to 6 years old), peer rejection predicts more difficulty in understanding faux pas in later years, while difficulty in understanding faux pas in older children (8 to 9 years old) predicts higher levels of peer rejection in even later years (Banerjee et al., 2011). On the other hand, early theory of mind understanding (for example, at 5 years old) tends to predict more adept social relations, higher peer acceptance, and lower rejection rates a few years later (Caputi et al., 2012). Thus, both directions of influence—from social cognitive capacities to peer relation quality and from peer relation quality to social cognitive capacities—may be at work at all ages, depending on the particular social capacities studied.

Developmental Patterns in Levels of Affiliation

Research on interactions with peers and other people beyond the family constitutes one of the largest areas of developmental psychology. Moreover, that research is increasingly being connected to other areas of research—such as the development of social cognition, theory of mind, and perspective taking, as well as to attachment patterns emerging from infancy. Individual differences loom large in much of this research and for very understandable reasons. We all are interested in the factors that made some children, including ourselves, popular or unpopular during childhood and adolescence and in whether there are long-lasting consequences of occupying one of those social roles. We have seen that questions about causes and consequences are extremely difficult to disentangle, even as researchers repeatedly document strong associations between some sociometric categories and a host of social, emotional, and cognitive factors.

It is important, however, to step back and remind ourselves that above and beyond the sometimes striking individual differences that are found, there are also very general patterns of development for peer interactions, relationships, and social groups that apply to virtually all children. We return to those patterns here as a way of keeping in mind this broader developmental perspective. Table 15.1 summarizes the major developmental findings for peer interactions that have been found over thousands of studies using the perspective of levels of affiliation (Rubin et al., 1998). It is only within the context of these broader developmental changes that we can understand how peer status categories emerge in childhood, change over time, and then gradually dissipate in later adolescence.

Social Network Effects

A different research tradition has begun to make important contributions to the study of the developmental effects of groups on behaviors. This line of work examines formal and quantitative properties of social networks to see if a person's position in the structure of a social network influences that person's nature. Social network effects were first documented most dramatically in terms of health patterns and group relationships. For example, one study found that the more obese friends you have, the more likely you are to be obese. More strikingly, if the friends of your friends are obese, those links can make it more likely for you to be obese. Finally, and most dramatically, even the level of obesity of the friends of your friends' friends can influence whether you are overweight (Christakis & Fowler, 2007). Over a period of 32 years, it was possible to predict the spread of obesity in a large social network based on friendship links that had as many as three degrees of separation from the person who was affected. In general, same-sex mutual friends tended to have the strongest influences on each other in terms of obesity, while different-sex friends did not have any measurable influence on each other in terms of obesity. Interestingly, at four degrees of separation, no significant effects were noticed. These results indicate that people who you do not know or may never meet can still influence your life through a form of social contagion of habits, lifestyles, or health-related behaviors.

More recent work has documented that such effects can also spread through social networks in adolescence (Ali et al., 2012; de la Haye et al., 2010; Fletcher et al., 2011; Fowler & Christakis, 2008; Valente et al., 2009). Thus, obesity in adolescents can be predicted from the prevalence of obesity among those who are as many as three links away from them in social networks. Similarly, eating habits strongly reflect network relations (Fletcher et al., 2011). There is every reason to suspect that such network effects start much earlier in childhood. Consider, for example, the ways that fads can spread wildly among schoolchildren in a neighborhood.

Subsequent studies have found three-link effects in social networks for a wide variety of behaviors, including smoking, alcohol use, exercise habits, and academic achievement, with many such effects now being demonstrated in adolescents and school-age children (Haas et al., 2010; Macdonald-Wallis et al., 2011; Mundt, 2011; Veenstra & Dijkstra, 2012). One strong effect occurs for happiness, with clusters of happiness appearing in networks (Fowler &

Level of Affiliation	0–2 years	2–5 years	5–11 years	11 years and older
Interactions	Not really social; more simply joint arousal Little reciprocal give-and-take High conflict	More elaborate patterns of play Increase in sharing, pretense, and orderly interactions	Large increase in frequency of social interactions Increase in size of peer groups Less adult supervision More single-sex interactions More interactions outside the home More verbal aggression and gossip; less pretend play	Peer interactions more influential and more frequent More cross-sex interactions
Relationships	Unique patterns of sustained interactions between pairs, but not really friendships	Children purposefully picking friends, usually choosing those most like themselves More prosocial with friends but also more hostile	Bullying Broader view of friendship, allowing for a more diverse range of friends and friendships	Recognition of nonexclusivity of friendships and granting of more autonomy to friends; thus, less jealous of friends' other relationships Increased intimacy with friends
Groups	Little evidence of group behavior	Dominance hierarchies; less overall aggression, but little explicit awareness of own status in hierarchy	Stable cliques; popularity hierarchies Social comparison more frequent and influential	Decreasing importance of cliques Increasing importance of integration of sexes

TABLE 15.1 Developmental changes in social affiliations. Children's social relations show distinct patterns of change during different developmental periods and across various levels, from interactions to relationships to groups. Adapted from Rubin et al. (1998).

Christakis, 2008; see Figure 15.11), and it is also possible to predict loneliness based on how peripheral versus central a person is to a particular network. These studies also show how happiness in a few individuals can spread through a network over time, with some fortunate indications that happiness spreads more robustly than sadness (Fowler & Christakis, 2008).

This new approach to group influences in development has great promise and offers the potential for major advances in the study of peer relations and groups. For example, it allows more formal analysis to be undertaken, which in turn enables quite precise predictions about effects. In addition, it illustrates for the first time how there can be effects at three degrees of separation from an individual and by people never encountered face-to-face in the person's lifetime. Finally, whether a person is central or peripheral in a network or has a dense versus a sparse set of connections may lead to interesting predictions about both social contagion and likely psychological states such as loneliness.

Media Influences on Development

Moving beyond face-to-face peer interactions and relationships, we now consider how the media come to have a socializing effect on children. The media can be intimately related to peer influences, suggesting how peers supposedly look and behave in a wide range of circumstances. The media can provide a large, albeit distorted, database for social comparison, suggesting, for example, typical levels of affluence and typical hobbies and styles. Media also can portray morally laden norms, such as appropriate ways to act both prosocially and aggressively. Television has long been thought to be the most influential medium, but in recent years, Internet communities and video games have also come to exert major influences on children. All of these influences in turn feed back on how peers interact with each other, whether it

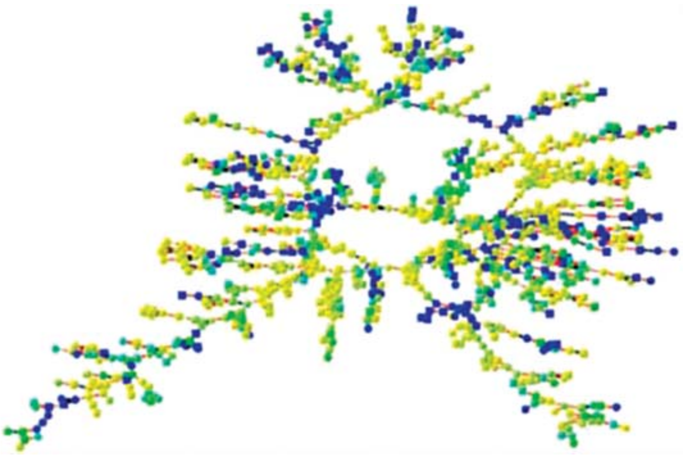

FIGURE 15.11 Social networks and happiness. Friendship relations in a social network can predict many facets of health and psychological states. This graph depicts "happiness clusters" by showing squares for males and circles for females and showing the connections of individuals with friends, spouses, and siblings. Siblings are shown as connected by black lines, and friends and spouses are connected by red lines. Yellow indicates happiness; blue indicates sadness; shades of green indicate moderate levels of happiness. Such graphs can be constructed for both adults and adolescents. People who are surrounded by other happy people tend to be happy. The researchers in this study found that happiness spreads through the network rather than simply occurring because of associating with other happy people. In addition, a peripheral (as opposed to a central) location in a network can predict loneliness. From Fowler & Christakis (2008).

is through social networking sites or through adopting the styles and values of a popular television show.

Television

Although television is prevalent, it varies dramatically in its content and how it influences children across their development. Any discussion of the possible influences of television on children must consider how influences vary both as a function of content and of age. Television can influence children in various ways, ranging from the cognitive to the emotional to the social. And these influences can be either positive or negative. On the positive side, television has the potential to teach children about the world, to encourage them to engage in prosocial behaviors, to give them practice in various forms of reasoning, and to facilitate language acquisition. On the negative side, television has the potential to hinder cognitive development, to impair prosocial behavior, and to foster antisocial and aggressive behavior.

Obviously, the effects must depend at least partially on the kinds of programs that children watch. Because educational programs make up only a small fraction of the television shows that most children watch, we need to ask about the overall effects of television in which entertainment programs dominate. In the discussions that follow, we will consider both the potential of television programming to have positive and negative effects when experimenters have children watch particular kinds of shows in experimental settings, and also the most common effects given the actual viewing habits of most children. But it is important to keep in mind the tradeoffs between experimental designs and naturalistic studies. Experimental studies, in which children are randomly assigned to one of two conditions, such as viewing violent versus nonviolent television, have the virtue of uncovering causal effects. They are also, however, often faulted for extrapolating from a situation in which children watch television for a few hours in a laboratory to real-life influences of television that may happen over thousands of hours and years of watching. Naturalistic studies have the obvious advantage of looking at real-life viewing habits that occur over appropriate time frames and viewing situations, but they have real limitations as well. If a correlation is found between, for example, viewers of violent television and higher levels of aggressiveness toward friends, it could be that television is causing the effect or it could be that aggressive children prefer to watch violent programming.

The Pervasiveness of Television Watching Watching television occupies a very substantial part of children's time in almost all cultures. Although the majority of studies of television viewing have occurred in North America, Japan, and Europe (since those regions were the first to have televisions in most households) television viewing has now spread throughout the world (see Figure 15.12). In the United States, there is at least one television in almost every home, and roughly 75 percent of those households subscribe to cable or satellite feeds, thus guaranteeing a huge variety of viewing options (Anderson et al., 2003). Moreover, in many households, television watching is the dominant activity in the home. Far more homes have the television on for several hours a day as opposed to 1 or 2 hours a week. An elementary school child in the United States typically spends 4 hours each day watching television. Counting weekends and summers, a child may spend far more time watching television than attending school, playing sports, or engaging in activities with the family (Comstock & Scharrer, 2006; Roberts et al., 1999). In addition to watching television shows, children also watch an enormous number of commercials, with a typical child seeing over 40,000 commercials a year (Kunkel, 2001).

Given the extraordinary prominence of television programming and advertising in children's lives, it is natural to assume that it must be having an influence on their development. Researchers have asked about the potential negative and positive effects of watching television. On the positive side, we can ask whether television can enhance cognitive skills such as attentional strategies, problem-solving

FIGURE 15.12 Television watching throughout the world. Although television was initially found primarily in the homes of those living in more developed countries, it is now a fixture in the lives of children in most areas of the world, even when there is no direct electrical service to a home.

routines, and literacy. We can also ask if television can improve prosocial behavior, such as sharing or resolving disputes. On the negative side, there has been extensive work asking if exposure to violence on television leads to both a greater tolerance of violence by children and an increase in violent behavior. Other studies have asked if television can impair aspects of cognitive development, such as attention, reading skills, and comprehension of complex narratives. Television does not simply reflect the culture at large. It is often a distortion of that culture, which may help create a distorted image of reality. In this discussion, we will try to give a modest sense of those other influences as well.

Q: Describe, in quantitative terms, the incidence of television watching by children in North America.

Changes in Television Watching with Age To understand how television might influence various aspects of a child's mind and behavior, it is helpful to first examine how a child develops the ability to extract information from television. Observe a child under 1 year of age in a room with a television. Even if older children and adults in the room are watching the television with rapt attention, the baby is unlikely to spend much of her time staring at the television screen. While quite young infants can extract some information from video monitors and even imitate facial expressions displayed on a monitor, imitation of complex actions takes more time to develop. For example, one study of 24- and 30-month-olds found that while they would imitate an action demonstrated by a television actor even after a 24-hour delay, they showed a considerably higher incidence of imitation when the actor was live as opposed to televised (Hayne et al., 2003). Another study found that 12-month-olds had considerable difficulty reproducing actions they had observed on a video monitor but could easily reproduce these actions when they saw them performed by a live actor (Barr & Hayne, 1999). The relative inability of younger children to learn as effectively from video as from live demonstrations is often called the **video deficit** and is repeatedly found across a wide range of studies (Anderson & Hanson, 2010; Kirkorian et al., 2008). In addition, it appears that infants younger than 12 months have difficulty telling the difference between coherent content and incoherent content in videos, such as the difference between a sequence that has logically ordered clips versus clips that are shuffled randomly (Anderson & Pempek, 2005; Kirkorian et al., 2008; see Figure 15.13). Thus, the narrative structure of most programs is not likely to be understood by infants younger than 12 months old. Detailed analyses of eye movements show that 1-year-olds have much more difficulty tracking changes from one scene to another, often requiring several seconds to orient to the new scene; as a result, they are unable to follow the unfolding narrative (Kirkorian et al., 2012). Similarly, 1-year-olds often have difficulty connecting what they see in videos with what is occurring in the real world, even when the relationships are very obvious to older children (Troseth, 2010).

FIGURE 15.13 Very young television viewers. Before 1 year of age, infants do not seem to be able to understand the narrative structure of programs and have difficulty telling the difference between randomly ordered clips and those that follow a thematic progression.

After infancy, children become much more dedicated television viewers, and the typical toddler spends several hours a day in front of a television. At approximately 30 months of age, a much larger range of programming may become comprehensible to the child and therefore of interest (Anderson & Hanson, 2010; Anderson & Pempek, 2005). Audiovisual presentations that are especially tailored to younger audiences—for example, "baby videos" that are marketed as enrichment materials—may well be of interest to children as young as 12 months, especially when adults are present who direct the infant's attention to critical actions and actors (Barr et al., 2008). The vast majority of commercial programming on cable television or networks, however, is usually only of interest to children older than 30 months. Obviously, highly complex plots and actions will continue to elude the understanding and imitative abilities of younger children, but at least by the time they are 3 years old, children can pick up on and reproduce relatively elaborate televised actions, often after considerable delays.

Q: How does the child's ability to absorb the content of television change with age?

Positive Effects of Television Television can transmit a great deal of beneficial information to children that can help them in their development. Such positive effects usually occur when children watch educational or other sorts of shows specifically designed to teach children—programs usually shown on nonprofit television channels. Children who watch prosocial and academic programming are somewhat more likely to perform better academically and to have better social skills (Calvert & Kotler, 2003). A major problem with evaluating the findings, however, is achieving true random assignment of viewers to watch different forms of television content. When studies show that children who prefer prosocial and academic television have positive outcomes, it is difficult to tell if there is another factor causing the children both to want to watch those forms of programming and to show better academic and prosocial skills. Far more compelling are studies that approximate experimental designs in which children are randomly assigned to watch different kinds of programming or to be part of groups that either have unrestricted television watching or limits to the programs they can watch. Nonetheless, such studies are less frequent than correlational studies because of the practical difficulties in carrying them out in naturalistic settings.

In terms of cognitive skills and learning, there are positive links to watching educational television. Children can learn vocabulary by watching television and video programs (Rice et al., 1990; Wright et al., 2001a), but the effects interact with programming content. In one study, when children viewed educational television between the ages of 2 and 3, they subsequently scored higher on vocabulary tests at 4 and 5 years, but when children between 2 and 3 watched more entertainment-oriented programs, their vocabulary was subsequently lower at 4 and 5 years than children who had watched less of such programming. This was not an experimental study with random assignment, but it did try to demonstrate statistically the causal effect of television viewing on vocabulary. Studies with experimental designs have also shown such effects. Yet, when children are younger than 2 years old, they often may not learn words from television that they can easily learn from live models (Krcmar et al., 2007; Zimmerman et al., 2007), even when they are viewing television and video programs targeted for children under 2 years of age. Thus, they still show the video deficit that is found in younger children. In general, there is little evidence that videos designed for children under 2 years of age actually teach them anything (Anderson & Hanson, 2010; Kirkorian et al., 2008).

Some educational television programs also appear to have positive effects on other cognitive skills, such as problem solving. For example, one popular program, *Blue's Clues* (see Figure 15.14), posed a problem at the beginning of each episode and then presented a story containing a series of clues; the viewer was then invited to see how the clues might be used to solve the problem. When children lived in a community that had *Blue's Clues* in its programming, they showed cognitive advantages on problem-solving tasks in comparison to children from a demographically comparable community that did not have the programming (Anderson et al., 2000). Viewing educational television that

FIGURE 15.14 Educational programming for young children. Television shows with a clear and well-designed educational mission, such as *Blues Clues*, which posed a problem to be solved through a series of clues, is associated with improved cognitive skills in younger viewers.

specifically aims to promote literacy also can have a positive effect with younger children (Moses, 2008).

The overall message about the positive cognitive effects of television is clear. If the content has a well-designed educational mission, it can have a positive effect on many aspects of cognitive development in children over 2 years old, perhaps especially for children from disadvantaged backgrounds (Huston & Wright, 1998). Children from low socioeconomic backgrounds may benefit more than advantaged children from watching educational television programs because they may encounter ways of speaking and situations that they are less likely to encounter at home than are advantaged children, and such exposure may help better prepare them for learning in school. If the content is designed primarily for entertainment and commercial value, however, it usually has negative rather than positive effects. This is unfortunate, given that children tend to prefer to watch entertainment programs (Comstock & Scharrer, 2006).

In terms of social effects, the message is quite similar. Educational television can have positive effects on prosocial behavior. There is some evidence suggesting that viewing programs such as *Sesame Street* can help young children gain a better understanding of different emotions and what sorts of factors are likely to give rise to those emotions. In addition, with the right kinds of programming, there may be modest influences on the ability to feel empathy for others (Wilson, 2008).

In general, prosocial behavior is more salient and frequent in educational as opposed to entertainment-oriented television, and the positive effects tend to occur in children who regularly watch educational shows. In experimental studies with random assignment, children assigned to watch prosocial television episodes are more likely to later show altruistic behavior, such as sharing, than are children assigned to watch episodes without obvious prosocial behavior. One meta-analysis of 34 studies found consistent positive effects of television shows that had prosocial content (Mares & Woodard, 2005). Other studies found that children who regularly watched shows such as *Mister Rogers' Neighborhood* or *Barney & Friends* were more likely to help another child with a difficult project than were children who watched programming without prosocial content (Friedrich & Stein, 1975; Singer & Singer, 1998). Across several such studies, it also appears that when parents point out to their children instances of prosocial behavior in educational programming, the act of commenting enhances positive effects in the children, quite possibly because prosocial actions are less salient or less comprehensible than violent actions and are therefore easier to miss without parental commenting (Wilson, 2008).

Even younger children may have some positive benefits of watching prosocial television, despite not fully comprehending it. For example, children between 12 and 18 months who watched *Sesame Street Beginnings* with their parents later had more frequent and higher-quality interactions with their parents in free-play sessions than did control children (Pempek et al., 2011). This indirect effect is not the same as an effect that directly increases prosocial behavior, and it may primarily reflect changes in parents, but it does show how a certain kind of positive interaction pattern between parents and very young children may get promoted if both watch a program that models such actions.

Finally, television may increase children's sensitivity to cultural issues and their acceptance of diversity in others. Educational programming often exposes children to a wider range of ethnic and racial groups than they might encounter in their daily lives, and it often portrays people from other ethnic groups in professional or social roles that might be different from what a child most commonly observes. Children who watch such programming tend to show more positive attitudes toward members of other groups and hold less negative stereotypes (Wilson, 2008). Of course, if a child mostly watches cartoon shows, there may be very little information that could create positive attitudes for diverse groups.

Q: Describe some ways in which television might present distorted impressions of social and cultural patterns in the world.

Negative Cognitive Effects of Television Most of the studies on the effects of television viewing have focused on the negative effects rather than the positive effects in regard to both learning and social behavior. For the most part, the negative effects tend to occur when children watch entertainment programming, which in the elementary school years and later years is by far the most common form of programming watched.

We have already seen some glimpses of the negative cognitive effects of television in our discussion of the positive cognitive effects. In general, when children are exposed to entertainment television instead of educational television, there tend to be negative effects on attention, problem solving, vocabulary, and literacy. For example, the same study that showed positive effects of educational television on attentional skills also showed negative effects of entertainment television on attentional skills (Kirkorian et al., 2008). Similarly, another study showed that 4-year-olds who were exposed to fast-paced cartoon shows for just 9 minutes showed deficits immediately afterward on executive function tasks, such as those involving delay of gratification, compared with children who had watched educational shows or engaged in drawing for the same period (Lillard & Peterson, 2011). Other studies have found a negative relationship between the amount of viewing of commercial television and vocabulary in very young children (Zimmerman et al., 2007).

One major source of concern about the negative effects of television revolves around achievement in school. If children are spending a great deal of time watching television, doesn't that activity take time away from academic activities, such as doing homework? Certainly, this is the message that many parents impart to their children. But the evidence for such effects is not strong. Television tends to displace other leisure activities, such as listening to the radio and going to movies, but not academic activities (Kirkorian et al., 2008). There are negative correlations between the amount of television watching and academic achievement, but closer analyses do not strongly support a causal link. For example, children from disadvantaged backgrounds tend to spend more time watching television, but a host of other factors associated with disadvantaged backgrounds may be influencing academic performance and not television per se. Again, without additional experimental studies, it is difficult to find strong evidence for a causal effect. Similarly, it is difficult to find clear evidence that entertainment television displaces time spent on reading and thereby reduces literacy. Although some older studies seem to suggest that such an effect occurred when television was introduced into one town and not into another, recent studies do not consistently show a causal relation between amount of entertainment television watched and reduced literacy (Moses, 2008). While there is a positive relation, there is no evidence supporting claims by some in the entertainment industry that entertainment television increases literacy.

Negative Social Effects of Television A great deal of violence occurs in television shows, and there are no indications that it is on the decline. One analysis compared the number of antisocial acts per hour on television in contemporary programming with that occurring 25 years earlier (Potter & Vaughan, 1997). There was a slight increase from 40.8 antisocial acts per hour to 42.1 antisocial acts. In addition, the content of violent programming is very different from reality. In the television world, violent acts are punished much less often, and violent actors are often more attractive and heroic than in the real world (Potter et al., 1995). Even the news portrays violence at far higher rates than it actually occurs in most people's daily lives (Anderson et al., 2003; Johnson, 1996; see Figure 15.15). By some estimates, a child at the end of elementary school is likely to have witnessed roughly 8,000 murders and over 100,000 other violent acts on television (Anderson et al., 2003, Condry, 1989; Huston et al., 1992). Ironically, cartoon shows for children show three times as much violence as violent entertainment television for adults (Wilson et al., 2002).

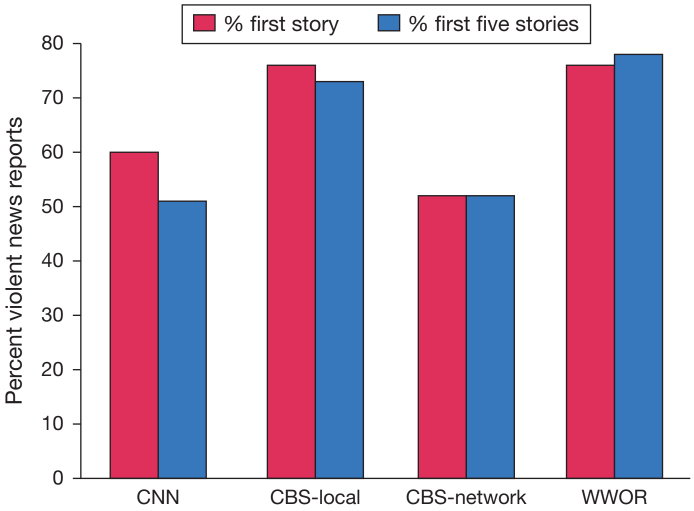

FIGURE 15.15 Violent television programming. News reports are heavily skewed toward reporting violent events. Adapted from Johnson (1996).

Does all this violence matter? Some writers have gone so far as to suggest that the violence in television is actually good because it gets everyday violence out of children's systems through the psychological mechanism of *catharsis*. The **catharsis hypothesis**, which was initially proposed in a much broader and potentially plausible account by Freud, argues that experiencing violence in a pretend setting is a form of release that makes it less likely that aggressive impulses will be released in real life. The catharsis hypothesis for television, however, has been repeatedly discredited (Bushman et al., 1999; Geen & Quanty, 1977). It is safe to say that violent television does not normally reduce aggression in viewers of any age. Moreover, many people believe, on some intuitive level, that violence on television increases aggression.

Q: What is the catharsis hypothesis, and what is the nature of the evidence about the effects of violent television programming on children?

The question of whether violence on television actually does increase aggression has been addressed in experimental ways, as well as in naturalistic studies, with the limitations inherent in both kinds of studies. As the total number of studies on the influences of television is well over 1,000, it is not possible to survey these studies with any degree of completeness. It is possible, however, to describe the overwhelming patterns found in both naturalistic studies and in experimental settings.

In naturalistic settings, the evidence normally must be correlational in nature. It is extremely difficult to make strong inferences about causation when experimental control is

	Adult Composite Aggression		Adult Physical Aggression		Adult Indirect Aggression	
Child TV measures	Men	Women	Men	Women	Men	Women
TV violence viewing	.21	.19	.17	.15	.03	.20
Perceived realism of TV violence	.22	.25	.14	.14	.05	.28
Identification with aggressive female characters	.15	.23	.05	.09	.01	.19
Identification with aggressive male characters	.29	.22	.14	.12	.05	.22

TABLE 15.2 Violent television viewing in childhood and adult aggression. Significant positive correlations are found between various measures of watching and identifying with television violence as a child and displaying both physical and more indirect forms of aggression as adults, with men showing more physical aggression and women showing more indirect aggression. Adapted from Huesmann et al. (2003).

lacking. Nonetheless, the naturalistic studies do show consistent correlations between higher levels of watching violent television and higher levels of aggression. For example, Table 15.2 shows one analysis of how viewing television in childhood was correlated with aggressive behavior 15 years later (Huesmann et al., 2003).

Unlike the experimental studies, naturalistic studies often have the appeal of looking at patterns of television viewing that occur over the course of several years, as opposed to an hour or two in a laboratory. Summarizing across many naturalistic studies, one meta-analysis of 400 studies on the relation between violence and television found a positive correlation of roughly .2 (Paik & Comstock, 1994; see also Hogben, 1998). As we will see shortly, even though a correlation of .2 means that most of the variations in violent behavior are not accounted for by variations in how much violent television is watched, it still represents a strongly significant effect for a population as a whole.

One classic study looked at links between how many hours adolescents spent watching violent television and the degree to which they reported engaging in aggressive behavior (Robinson & Bachman, 1972). Other studies have found correlations between watching violent television in childhood and engaging in aggressive behavior as adults many years later (Huesmann et al., 1984). As we have repeatedly seen, the obvious question in such cases is whether viewing aggression on television is causing children to become more aggressive or whether children who prefer violent television are also those who prefer to be aggressive throughout their lifespan. Thus, it is possible that some intrinsic aggressive tendency, or perhaps one that is socialized into the child by factors other than television, may lead the child to watch more violent television and to exhibit more aggressive behavior, without the television violence actually causing increases in a child's aggression. It is difficult to fully address this concern in nonexperimental studies, but statistical analyses designed to tease out evidence for causal effects do suggest that watching violence on television causes more aggressive behavior (Anderson et al., 2003; Huesmann et al., 2003).

An alarming pattern occurs across all the nonexperimental studies: the correlation between violent television watching and aggression seems to be rising. As seen in Figure 15.16, the rise has been most dramatic since 1995. One possible explanation for the rising correlation is simply that the quality of studies is improving and that the relation is being measured with increasing precision and is coming closer to the correlations found in carefully controlled experimental studies (Bushman & Anderson, 2001). An alternative explanation is that somehow aggression on television is becoming more influential on children's behavior, perhaps as expertise in programming and special effects increases.

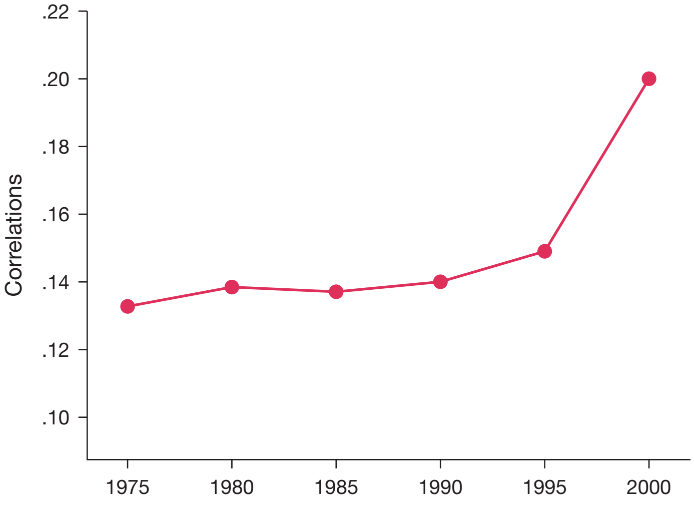

FIGURE 15.16 How watching violence on television correlates with violent behavior. This graph shows the cumulative correlations over the years between watching violent shows and violent behavior. As studies accumulate, the correlation has risen substantially, especially since 1995. Adapted from Bushman & Anderson (2001).

Experimental studies of the relationship between television and aggression allow us to more directly infer causation, even as we lose some of the naturalistic realism of the studies. In general, the experimental studies tend to show stronger effects of watching violent television than do the naturalistic studies. Recall from Chapter 12 the classic studies of children's inclination to model aggressive behaviors of adults after watching film clips showing adults beating up a toy Bobo doll (Bandura et al., 1961). In the years since those early studies, other experimental studies have shown similar relationships between observing violence on film and television and acting aggressively.

Aggressive behavior might increase because children start to accept higher levels of violence as normal, a process often called **desensitization**. One particularly chilling study had 44 fourth-graders watch either violent or nonviolent programming (Drabman & Thomas, 1974). All fourth-graders were then taken to a room where they were led to believe that they were keeping an eye on younger children in another room by observing them on a video monitor linked to a camera in the other room. In fact, the video monitor was not playing a live broadcast of events in the other room, but rather a filmed sequence of staged events in which there were gradually escalating violent physical actions. The children in the room initially played quietly together, but then they became increasingly destructive and engaged in more physical abuse toward each other, with the tape ending as they seemed to destroy the camera. The experimenters measured how long it took for the fourth-graders who were observing the monitors to seek out adult help to respond to the situation and whether they did so when physical abuse between the children was first seen. There was a strong effect from the sort of television programming that the fourth-graders had watched. Those who had watched violent television were much less likely to seek out adults when physical abuse first occurred, and they took much longer to seek out adult help. It appeared that those children had come to regard a much higher level of violence as acceptable.

Desensitization studies of this sort in both television and video game media demonstrate that children, as well as adults, can start to take certain levels of violence for granted if they watch enough of it on television (Carnagey et al., 2007). But desensitization does not in itself lead to increased aggressive behavior. Perhaps viewers of violent television shows stop noticing violence in others but still are just as restrained in committing it themselves. Indeed, it could even be argued that desensitization reduces the chance that individuals see the acts of others as aggressive and overreact—that is, desensitization may make their "fuse" longer and slower. In reality, most experts suspect that desensitization increases the tendency to violence by making the experience of violence a less aversive emotion, but there are not yet any definitive studies showing a link between desensitization and increased violent behavior (Anderson et al., 2003).

There is substantial evidence from a wide range of studies for a link between watching violence on television and increases in violent behavior. One classic laboratory study showed elementary and middle school children programs that varied in levels of violence and then presented them with scenarios in which they were asked to choose between one of two possible actions. For example, a researcher describes a situation to a child in which someone comes up to him and calls him names and then asks the child whether it is better to engage in one of two actions in response, such as hitting the person or telling an adult about the incident. The results clearly indicated that violent actions were chosen more often by viewers of violent episodes (Leifer & Roberts, 1972).

When children are compared with adults, the effects of violent television on children are often longer lasting than the effects on adults. When adults view violent television, they may experience a brief increase in arousal and priming of aggressive thoughts and actions; when children view violent television, it appears that they learn new, long-term methods for dealing with difficult situations, as well as a general desensitization toward violence (Bushman & Huesmann, 2006; Huesmann, 2007). This difference in age effects has important implications for studies that attempt to generalize results from adult studies to children.

Q: Describe the overall findings of naturalistic and experimental studies on the effects of violent television programming on children and describe the tradeoffs of each approach.

It is, of course, difficult to determine just how much violence researchers can ethically elicit in children, especially of the interpersonal sort. Nonetheless, the vast majority of studies indicate that a substantial increase in physical and verbal aggression can be created in laboratory tasks by exposing children to violent programming (Anderson et al., 2003; Bushman & Huesmann, 2012; Comstock & Scharrer, 2006; Wilson, 2008). Despite these repeated results, however, some critics argue that the real-life effects of violent television on individual children are not that large and that researchers make too much out of the negative effects of violence in the media (Freedman, 2002; Gunter, 2008). This criticism is an important one that must be acknowledged. In the research literature, correlations at or near .3 between violent television watching and aggression are on the high end of the measured effects. This means that most of the time there will not be an observable effect of violent television programming on any given child's behavior. Statistically, only 10 percent of the variance in a child's aggressive behavior would be accounted for by a .3 correlation. Thus, even if a child spends every day of his summer vacation watching extremely violent television, the odds are that this experience will not lead to behavior problems in the child.

At the same time, when television violence is viewed as a public health threat in the same way as biological factors, its impact seems quite large (see Figure 15.17). Instead of asking about the likelihood of any given child engaging in violent acts as a result of watching violent television, we can instead ask whether, in a population as a whole, there will be a greater incidence of violence as a result of violent programming. Thus, if we consider a metropolitan area of 10 million people (such as the greater Chicago area), we can ask how many more violent events might occur because of a positive correlation between violent television and aggression. Considered that way, even a correlation of .2 could still mean that hundreds of additional incidents of violent behavior would occur in that region. In this manner, the effects of violent programming are considered in the same way that smoking is considered as contributing to lung cancer. Even among heavy lifelong smokers, the odds are that the smoking will not lead to death from lung cancer. Although the lifelong smoker is much more likely to die from lung cancer than a nonsmoker, the correlation is still far from 1. It is true, however, that a smoker is more than 10 times as likely to die from lung cancer as a nonsmoker. When watching violent television is viewed in this way, the public health threat of violence on television can be construed as one of the largest threats in the United States, second only to that of smoking. There is a stronger correlation between media violence and aggression than there is between condom use and sexual transmission of HIV, exposure to lead and IQ scores, and exposure to asbestos and laryngeal cancer (Bushman & Anderson, 2001). It is striking, especially in the wake of massive legal settlements in areas such as smoking and asbestos exposure, that the effects of media violence have never been adequately addressed. If, for example, studios and networks produced and distributed violent shows while fully knowing that such programming increased violent behavior, others might well hold them accountable for such actions. Indeed, some legal scholars have suggested that television should be treated as a "toxic environment" for children in much the same way that more traditional chemically toxic environments are treated (Woodhouse, 2004).

Q: If violence on television is considered a public health threat analogous to biological threats, how serious a threat does it seem to be relative to those other threats?

Responding to the Influences of Television Violence

Given that violence on television does seem to increase levels of aggression in many viewers, what options are open to parents to limit the effects? One option is to try to limit access to violent programming. In practice, this is difficult to do. Children often watch television in public places or at friends' houses, venues where parents have little or no control. In addition, it is not always obvious from the name of a program that there will be extensive violence in its content. Even in their own home, parents may have difficulty restricting access to violent television. They are certainly not present at all times when their children are watching television, and few parents have the time to carefully censor the content of all shows their children watch.

More official attempts to allow regulation of violence have not been widely implemented. In 1996, the U.S. Congress passed legislation requiring manufacturers to install V-chips in all television sets with screens larger than 13 inches by January 1, 2000 (see Figure 15.18). Despite unfounded opposition based on the claim that the chips would significantly add to the price of television sets, V-chip technology was soon made available in all television sets at virtually no increase in cost. Programs were rated by networks for level of violent and sexual content, and parents could select the level of violence they were willing to have on their televisions. This technological innovation, however, led to little real-life use by parents (Hazlett, 2004). Parents were mostly

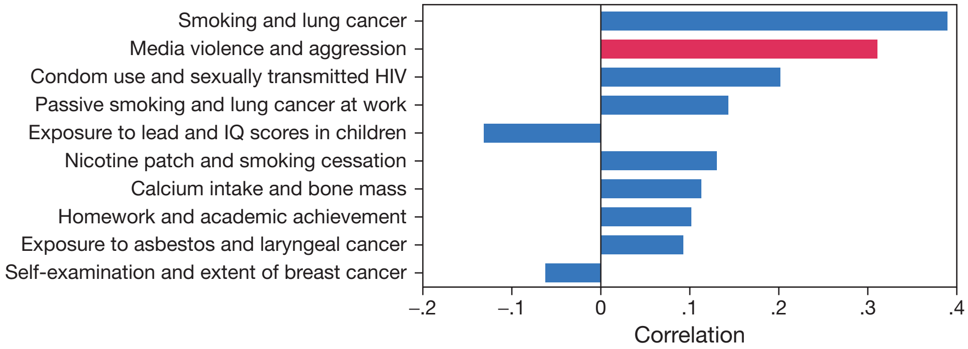

FIGURE 15.17 Television violence as a public health threat. When the correlations (both positive and negative) between various behaviors and outcomes are compared, the correlation between media violence and aggression is larger than all other major public health threats except for the correlation between smoking and lung cancer, which is only modestly higher. Adapted from Bushman & Anderson (2001).

FIGURE 15.18 Filtering out television violence. In 2000, following a recommendation made by President Clinton (shown here holding up a V-chip), the U.S. Congress mandated that all new television sets had to contain a V-chip, which could be set to filter out television shows containing different levels of violence. Even though most televisions soon had such chips, only a tiny percentage of parents ever programmed their televisions to limit their children's access to violent programming.

unwilling to learn the new techniques for programming their televisions to block violent shows or did not want to deal with the hassles of having to turn the violence filters on and off for different viewers. Some cynical commentators have suggested that the V-chip was largely intended to be a public relations maneuver to placate V-chip advocates without ever threatening the ratings of television networks. That argument gains credibility given the minimal effect of V-chip technology. An additional side effect of censoring television violence in the home, whether by means of the V-chip or some other intervention, may be to make such programs become more desirable ("forbidden fruits") to the children who are not allowed to watch the programs at home. Although there are no systematic studies demonstrating such a possibility, parents do report that their children become especially eager and attentive audiences of forbidden shows when at their friends' houses.

Another option for parents who want to limit the effects of violent television programs is for the parents to attempt to reinterpret the violent content of shows or to make the shows less attractive to their children. Some studies do indicate that when parents watch shows with their children and voice concern over the violent episodes as they occur, children who might otherwise be at risk end up being less violent (Anderson et al., 2003), but extensive work has not yet been done in this area. Moreover, it is difficult for many busy parents to consistently watch television with their children (as well as being aversive if the parents do not enjoy the content!).

In the end, censorship of content by parents or joint watching and commenting by parents may mitigate somewhat the influences of television violence on aggression in their children, but the effects of these interventions are likely to be modest given the practical difficulties involved. A more dramatic effect might occur if viewing of television of any sort were heavily restricted. But to avoid being hypocritical, parents would also need to cut back on their own viewing habits, and most are not willing to do so. Moreover, television acts as a form of "electronic babysitter" for many parents who are unable to engage in more interactive encounters with their children. Children are usually remarkably passive and docile when lounging in front of a television set (Condry, 1989), and this tranquilizing effect is not lost on parents or on car manufacturers, who routinely include small video displays as a highly attractive option in the family minivan.

Q: Describe at least two different approaches to reducing the effects of television violence on children. How effective have these approaches been?

Stereotyping in the Media While the vast majority of research on the effects of television has focused on how violent content increases aggression, the effects of television may also involve gender, racial, and lifestyle stereotyping. Television programming shows young, traditionally attractive women far more often than their representation in the population and more often than it does so for men (Witt, 2000). When couples are shown, the casting director picks women who are considerably younger than the men, even if the ages in the script are meant to be quite close, thus conveying a sense that married women should look younger than they actually are. In addition, the average television or film actress is far more likely to have had extensive cosmetic surgery than is the norm in the general population, again creating a distorted image of body appearance.

Women and girls are generally portrayed as less smart and more submissive than men, and physical attractiveness is conveyed as more essential to a woman's worth (Witt, 2000). Women's marital status is usually clearly indicated, while it is often ambiguous for men. Men are more frequently portrayed in leadership roles or as being pivotal to a decision or change in events. The same stereotypes occur in advertising. Although there are some recent exceptions in which women are portrayed in smart, strong roles (for example, as judges, lawyers, doctors, and even as the president of a country), these are exceptions to a general pattern that has been consistent for decades (Collins, 2011). Moreover, across several types of media, there is an increasing trend to portray women, but not men, in explicit sexual roles (Bleakley et al., 2012; Hatton & Trautner, 2011).

It is commonly believed that such depictions give children distorted images of norms of appearance, affluence, and even diet. There are also frequent claims that the media pressures young women to engage in certain behaviors, pushing some into anorexia (Hamilton & Waller, 1993; see also Groesz et al., 2002; Kilbourne, 1994; see Chapter 17). One particularly dramatic suggestion of such influences arose from a study on the introduction of television into a rural community in Western Fiji in 1995 (Becker, 2004; Becker et al., 2002). In 3 years, exposure to prime-time soap operas featuring young female characters who were all attractive and thin was associated with a rise from almost no weight-conscious behaviors to 15 percent of adolescent girls reporting using induced vomiting to control weight and 69 percent reporting having been on diets (see Figure 15.19). Roughly half the girls thought that they were too fat. It certainly appeared that television had ushered in a new set of views of the preferred female body.

Television may also influence perceptions of norms of affluence and consumerism. The protagonists in most shows tend to be more affluent than most people in North America, let alone in other parts of the world (Taylor, 1989; Yang et al., 2008). Moreover, the activities of the protagonists are often consumer based, including shopping and attending events and clubs, and rarely show activities such as doing homework, household chores, or working at a desk (Anderson, 1995). In many ways, this bias is hardly surprising, as much of real life does not make good entertainment. But it may convey an impression to viewers that their lifestyles are out of line with the "norms" presented on television. Given frequent claims of how television might distort children's perceptions of various norms (Woodhouse, 2004), there is a clear need for more focused experimental research on such issues.

FIGURE 15.19 The introduction of television into rural Fiji. One study documented a close association between the introduction of U.S. network television programming into rural areas of Fiji and a very substantial rise in weight-conscious behaviors, ranging from dieting to eating disorders. The associations were primarily found for girls in late childhood and the teenage years.

Video Games, Computers, and the Internet

One of the most dramatic changes in recent years has been the surge in the use of video games, computers, and the Internet by children in developed countries and, increasingly, in developing and undeveloped regions. In addition, because the Internet and games can now be accessed not just through computers, but also through tablets and smartphones, many children are connected and playing games almost every waking hour and in every possible location. The patterns of usage are now so extensive that they have led researchers to initiate a wave of studies on the effects of these forms of media on children. Although the studies and effects are quite similar in many ways to research on television, there are important differences related to intrinsic properties of these forms of media, most notably their interactive features.

Video Games Playing video games now rivals the time children spend watching television (Rideout et al., 2010). The emerging literature on video games generally suggests that the effects of video games can be both more positive and more negative than the effects of television, in essence amplifying influences when a child is an active participant in a game as opposed to a passive viewer. In addition, as video games become ever more realistic and engrossing, their effects may increase as well (Greitemeyer, 2011). Finally, just as with television, the content of the video games is critical to whether they have positive or negative effects.

One surprising positive change that differs from the effects of television viewing involves improvements in attention skills, such as noticing objects and avoiding distractors (Green & Bavelier, 2003; Powers et al., 2013). Moreover, people with extensive experience playing video games can have a distinct advantage in learning laparoscopic surgical techniques that involve manipulations of robotic arms via joysticks and other computer interfaces (Rosser et al., 2007). This is hardly to say that aspiring surgeons should devote more energy to video games than to traditional academic experiences, but it is intriguing that, as surgical techniques increasingly use video and robotic interfaces, those techniques may come to draw on skills derived through extensive experience with video games. In many areas of expertise, it can take several thousand hours of practice to reach high levels of proficiency (Ericsson & Charness, 1994). Comparable effects of video

DEVELOPMENT AND SOCIAL POLICY

Free Speech and Children's Rights

A discussion of children and the media should consider not just the media that children are exposed to but also the media that children produce. One of the most controversial topics in social policy concerning children involves restraints on what children are able to say and write. This topic brings into play issues concerning the moral development of children, the development of impulse control, and peer aggression, among many others. It also raises questions about whether children should be restricted in their own speech so as to protect others from that speech, and it thereby again introduces issues concerning the influence of media on children, even when it is produced by peers.

In many countries, free speech is one of the most cherished rights of its citizens. It may therefore seem ironic that free speech is not guaranteed for children and adolescents in some contexts, most notably in the schools. The legal rationale against granting free speech to children is based on theories about children's cognitive and social development as well as ideas of promoting the educational mission of schools. In 1988, the U.S. Supreme Court decided in *Hazelwood School District et al. v. Kuhlmeier et al.* that a group of high school students who were members of the Hazelwood East High School, in St. Louis County, Missouri, did not automatically have the protection of free speech and that the high school's principal was allowed to forbid publication in the school newspaper of items that he thought might embarrass members of the school community (for example, the effects of divorce on families) or that might be inappropriate for younger readers of the paper (for example, discussions of birth control and sexual activity).

Why was free speech not guaranteed in a high school newspaper, given that it is usually allowed on college campus newspapers? Why should high school students be forced to "shed their constitutional rights to freedom of speech or expression at the schoolhouse gate" (*Tinker v. Des Moines Independent Community School District,* 1969)? Some cases are related to concerns that the school newspaper might contain material that would be inappropriate for younger readers at the school, but many other cases simply involve speech that is uncomfortable for the faculty and administration of a school or that is perceived as "disruptive to the educational mission of the school" (Garnett, 2008). The notion of disruption, however, can be difficult to define and often seems to involve assumptions about how the immaturity of minors makes them more easily influenced. In one highly publicized case (*Morse v. Frederick,* 2007), a student in a public high school in Juneau, Alaska, was suspended from

game experience are now being found in other domains as well, such as learning how to remotely operate drone aircraft (McKinley et al., 2011).

Given that many children start playing video games before they even enter school, the cognitive effects of playing such games that are seen in adolescents may be building on many years of prior experience. Any adult without video game experience who tries to learn a new game along with a child rapidly realizes how much he is at a disadvantage as a learner. Children may have years of expertise gained from playing a wide variety of video games that gives them a huge head start even for learning a completely novel game.

Many video games are designed to teach specific skills, such as mathematics skills (Lopez-Morteo & Lopez, 2007) and various science topics (Minton, 2008). When the games are well designed, they usually have strong educational benefits (Swing & Anderson, 2008). In addition, video games have successfully been used to facilitate instruction in military strategy and operations, disease management, and of course airplane piloting. There are few popular video games that focus on prosocial behavior and even fewer studies of the positive effects of such games. But based on findings about the effects of prosocial television shows, researchers expect to find comparable if not even stronger effects of video games that reward prosocial, nonaggressive behavior (Wilson, 2008). In fact, such effects are now being uncovered by researchers. For example, one study randomly assigned college students either to a prosocial video game in which their goal was to take care of small creatures or to a neutral game involving falling shapes (Tetris). Later, the experiments staged an aggressive encounter between people in the laboratory and measured the likelihood of the game players to intervene. Those who had previously played the prosocial version intervened more than half the time, while those who had played the neutral game intervened only one-fifth of the time (Greitemeyer & Osswald, 2010). Other studies have shown that even when playing violent video games, if the players form cooperative teams, some prosocial school when he held up a banner with the phrase "BONG HiTS 4 JESUS" as an Olympic torch was being carried down the street (see Figure 15.20). Even though the student did not display the banner on school grounds, the U.S. Supreme Court ruled that the suspension was constitutional. The Court ruled that the banner's message had the potential to be disruptive to the school because it might encourage students to engage in illegal drug use. The same behavior by a college student or a town resident would be protected under the First Amendment to the U.S. Constitution. What is it about younger children that suggests that they should be treated differently?

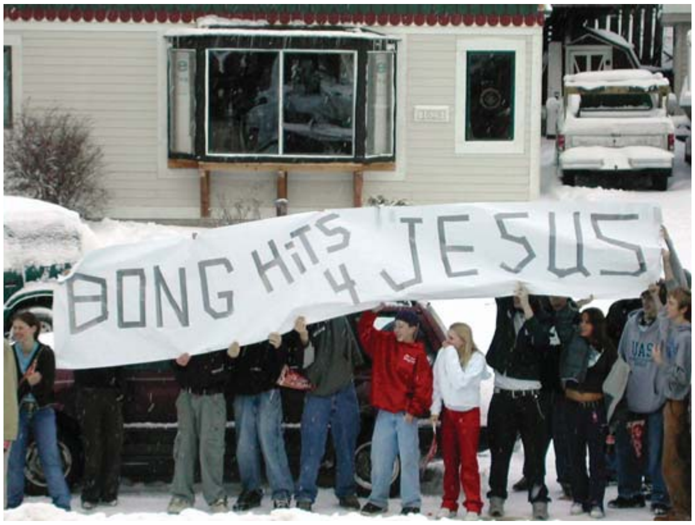

FIGURE 15.20 Freedom of speech and minors. When a group of high school students unfurled a provocative banner on a public street while a parade passed in Juneau, Alaska, a student from an area high school was suspended for holding up the banner. The case, which was heard by the U.S. Supreme Court, raised fundamental questions about why the developmental status of minors should curtail some rights concerning free speech.

The challenge here is knowing what is appropriate in terms of constraints on what children are allowed to say or have access to (Hudson, 2004). Some, for example, have argued that in the post-Columbine era, students' rights, free speech among them, are being trampled through such actions as censorship in attempts to ensure their safety (Calvert, 2000). It would seem that the only way to have informed opinions about when to curtail such rights would be to have better research on a host of developmental questions. In particular, is there something about younger children that requires that they need protection from certain kinds of information while older youth do not? In what ways are the taste and judgment of younger children deficient and in need of monitoring? Are aspects of children's ability to engage in moral reasoning relevant to their entitlement to free speech? As children and adolescents have ever-increasing access to public forums through such means as Internet websites, blogs, and social networking, the challenges of constraining their free speech appropriately are also increasing. Scholars are now asking how developmental psychology might inform debates about the boundaries of free speech for children and adolescents (Levesque, 2007).

behaviors may also be promoted in later tasks (Greitemeyer et al., 2012). The authors of these studies strongly suggest that such positive effects of prosocial games should also be found in quite young children, but large-scale experimental studies still need to be done with younger populations.

When video games contain violence, they may facilitate aggression even more than television programs, as video games foster and train active aggression as part of the experience rather than offering passive viewing, as is the case with television. A child learning to play a video game becomes more and more skilled at killing, maiming, and brutalizing other agents, many of which can look like normal humans. Although the body of research on video games and aggression is less extensive than that on television, most reviews of the research conclude that, similar to the findings with television, there is a relation between the time spent playing violent video games and increased levels of aggression. Moreover, the relation is found in both naturalistic studies, where causation is more difficult to infer, and experimental studies, where the causal influence is much clearer but the effects are more likely to be measured only on a short-term basis (Anderson & Bushman, 2001; Gentile & Anderson, 2006; Sherry, 2001; Swing & Anderson, 2008). Researchers suggest that the same clusters of factors that mediate the influence of violent television on aggressive behavior are at work in video games as well, including desensitization, arousal, priming of certain actions and response tendencies, and learning new ways to aggress (Anderson et al., 2010; Swing & Anderson, 2008). In addition, researchers have argued that video games have properties that may cause greater effects than television. These properties include increased identification with the aggressor (in many games the player can pick an aggressor that he identifies with), active participation, rehearsal of aggressive actions from start to finish, direct rewards for engaging in violent behavior, and a much higher incidence of violent episodes per hour. Heavy involvement in aggressive role-playing games on the Internet may have similar effects (Holtz & Appel, 2011; Krahé et al., 2011; Lee et al., 2010). In some experimental studies with children, simply playing violent video games for a few hours can increase levels of both aggressive cognition (speed of accessing violent concepts) and aggressive behavior, such as deciding on harsh punishments for opponents in games (Anderson et al., 2007). Playing violent video games also results in decreased empathy and prosocial behavior, with these effects apparently equally strong in both males and females (Anderson & Hanson, 2010).

In short, although video games have great potential for positive effects, ranging from well-documented influences in cognition and learning to effects in the prosocial realm, they also can have well-documented negative effects, depending on the content of the games. In particular, when the games contain violence, as the vast majority of popular video games do, they increase aggressive thoughts and behaviors in children at least as much as watching violent television shows does and quite possibly a good bit more.

Internet Communities In a relatively brief period of time, a whole new kind of community has emerged that children and adolescents, as well as adults, have joined in droves: social networks on the Internet (Subrahmanyam & Greenfield, 2008). Although social network sites such as MySpace and Facebook officially prohibit users younger than 14 or 13 years of age, assessments of real users suggest that many of the users are quite a bit younger (Rosen et al., 2008). By some estimates, almost 40 percent of children between 9 and 12 years old use Facebook (Livingstone et al., 2011). In addition, while many children and young adolescents are using social network sites to create communities of friends and role-playing groups, and while parents report that they are concerned about what goes on in such Internet communities, in practice most parents are unaware of what their children are actually doing when logged onto such communities (Rosen et al., 2008). More broadly, in developed countries, and increasingly in developing countries, many children are using the Internet by the fourth grade, through e-mail, instant messaging services, chat rooms, and other ways that connect individuals (Blais et al., 2008; Lenhart et al., 2001). When simple access to the Internet of any type is examined, even 25 percent of 5-year-olds have some access (see Figure 15.21). In addition, use of the Internet for such activities as chat rooms, instant messaging, and role-playing games occurs widely across the entire socioeconomic spectrum (see Table 15.3).

Scholars have been divided over the effects of Internet activity on social development. Some suggest that social interactions on the Internet are a poor substitute for real-world social interactions and result in weakened real-world social relationships and loneliness (Kraut et al., 1998). Others propose that the Internet provides opportunities for maintaining, enriching, and discovering new social relationships and thereby enhances social relationships, intimacy, and a sense of belonging to a community of peers (Valkenburg & Peter, 2007). One possible consequence is that children and adolescents are likely to disclose personal details about themselves to relative strangers far more quickly online than in person (Bargh et al., 2002; Gross et al., 2002), with the possible effect of forming much more intimate friendships in a shorter period of time while not really having those people as normal friends.

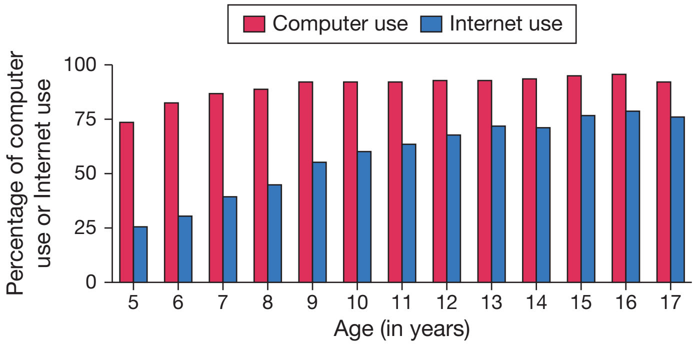

FIGURE 15.21 Percentage of computer use or Internet use by age. In the United States, the use of computers and the Internet has become widespread. Even 25 percent of 5-year-olds in 2001 used the Internet. From DeBell & Chapman (2003), based on data from the U.S. Census Bureau (2001).

A closer look at Internet use patterns by children and adolescents suggests how proposals for both negative and positive effects may be true in specific contexts. In particular, we can partition social interactions on the Internet into two kinds: those that continue relationships developed in the real world, taking them into the Internet via e-mail, instant messaging, and status updates, and those that involve meeting strangers online via chat rooms and social networking sites (Blais et al., 2008). The use of the Internet to support already formed real-world relationships generally seems to have positive social benefits, with children and adolescents experiencing stronger and more satisfying social relationships in ways that seem to build and enhance friendships and romantic relationships (Manago et al., 2012; Reich et al., 2012). In contrast, those who form new relationships with strangers online generally find them to be less satisfying and experience increased alienation and lower-quality friendships. While it does appear that the majority of children use the Internet to build on existing real-world relationships, as many as a quarter of those in some age groups may focus on developing friendships with strangers (Blais et al., 2008). Moreover, in some cases, patterns of online media usage are related to negative social outcomes. For example, one study of over 3,000 girls between the ages of 8 and 12 found that girls who showed high use of Internet media, especially online videos, experienced increased negative social interaction (they had trouble making friends or engaging in social activities and disapproval by their par-

	Family Income				
Internet activity	Less than $20,000	$20,000–$34,999	$35,000–$49,999	$50,000–$74,999	$75,000 or more
Completing school assignments	63.5	65.8	68.7	73.2	78.2

TABLE 15.3 Internet use patterns (shown as percentages) and socioeconomic status. Usage patterns of the Internet are quite similar across various socioeconomic groups, with a tendency toward higher usage rates in most categories for more affluent children. Adapted from DeBell & Chapman (2003), based on data from the U.S. Census Bureau (2001).

ents of their friends). In contrast, higher levels of face-to-face communication were associated with more positive social well-being (Pea et al., 2012).

Other studies suggest that a primary focus with online friends can lead to a form of "Internet addiction" in which children of both sexes seem to become intensely preoccupied with online activities as opposed to face-to-face interactions (Smahel et al., 2012). Most children, however, seem to use the Internet in a manner that helps promote and maintain offline relationships. In addition, only a relatively small number of children seem to engage in Internet activities that are unsafe with respect to exposure to either inappropriate content or individuals (Valcke et al., 2011). For parents who are concerned about the time their children are spending on the Internet, it is clearly important to get a sense of what activities their children are engaging in to assess whether they might be harmful. As noted earlier, the vast majority of parents find it difficult to monitor Internet activity at that level of detail. Fortunately, the early fears of children being exposed to nearly continuous hazards seem to be heavily exaggerated.

One troubling pattern in Internet activity among children and adolescents is known as **cyberbullying**, a form of aggression over the Internet, often by a group against an individual (Li, 2007; Ybarra & Mitchell, 2004, 2008). Cyberbullying can occur in real time as users gang up on one another in an instant message board or chat room. It can also occur over longer periods by posting hurtful messages or graphics on Web pages or bulletin boards. Cyberbullying raises concerns because of the ways it departs from real-world bullying (Menesini & Spiel, 2012). Cyberbullies can be anonymous, they can search out a wider range of vulnerable targets, and they can more easily find willing accomplices. The potential to embarrass or humiliate another person can be greatly exacerbated by having a much larger audience to witness the event. In addition, cyberbullying tends to be even less monitored by adults, who may be largely oblivious to harsh bullying that would be noticed in the real world. This may be a particularly acute problem because incidences of bullying can spiral out of control in a community when parents and school authorities have little or no awareness that it is happening. Finally, any feelings of empathy that might be triggered when a victim is being bullied face-to-face are not likely to be triggered on the Internet (Li, 2007; see also Blais, 2008; Patchin & Hinduja, 2006; Smith et al., 2008, for related discussions of the unique aspects of cyberbullying). Moreover, cyberbullies report lower feelings of remorse for their actions than do bullies in the physical world (Slonje et al., 2012).

It appears that bullies on the Internet are often the same individuals who engage in bullying in the real world (Blais, 2008; Gradinger et al., 2009; Olweus, 2012; Vazsonyi et al., 2012). The effects of cyberbullying seem quite similar to those of real-world bullying, with victims showing decreased levels of social belonging and a worse quality of social life at school. In addition, because cyberbullying is usually a form of relational social aggression, it appears to be practiced more by girls than by boys (Blais, 2008; Smith et al., 2008; Sourander et al., 2010). Taken together, the research on cyberbullying suggests that parents and other authority figures need to maintain their own presence on the Internet and a level of Web literacy if they are to have some influence in stopping inappropriate aggressive behavior between peers on the Internet.

The effects of cyberbullying can be so devastating as to compel a victim to commit suicide. In a widely publicized case in 2006, Megan Meier, a 13-year-old girl, was befriended by a "Josh Evans" on MySpace. But Josh Evans was a fictitious name invented by the mother of a former friend of Meier who was worried about what Meier was saying about her daughter online. After initially sending Meier friendly messages, the mother and others had "Josh Evans" turn on Meier and reject her on the website. The rejection was seen as leading to Meier's suicide. This case also illustrates how bullying of a child can sometimes not just come from peers but from adults as well when they think their identities can be concealed. In short, cyberbullying has the potential to amplify the effects of offline bullying in devastating ways. But it is important to also understand that its prevalence is far less than traditional bullying, that the extreme sensationalized accounts are very rare, and that very often the same individuals are involved in cyberbullying and traditional bullying (Olweus, 2012).

Q: How might the greatly increased presence of computers, Internet access, and video games influence the social development of children?

Roles in the Larger Culture

In addition to the influences of various specific factors on children, such as television, video games, and peers, the broader culture as a whole can exert its own influences on children, influences that may largely be invisible to those within that culture but obvious to those outside it. These influences can be seen as setting up certain roles that all members of that culture are expected to play in social interactions. We will consider roles that apply similarly to all members of a culture or subculture, as well as roles that seem to be organized around gender. Throughout this book we have considered cultural and gender differences in specific contexts as they arise, but it is useful in this chapter to consider cultural and gender roles more directly. A major theme of this chapter is the influences of ever-widening communities on the developing child. We therefore will ask how cultures and subcultures can cause children to come to adopt certain "lenses" on reality that result in their interpreting situations and adopting values quite differently from those who come from different backgrounds. In addition, we will see how socialization of attributional styles, as discussed earlier this chapter, can be a mechanism of immersing a child in a cultural role.

Distinctive Cultural and Subcultural Roles

One example of the role played by culture is seen in how children who grow up in the southern United States react to insults as opposed to how children in the rest of the country react to them. The culture in the South has been labeled a **culture of honor** in that many people in the South endorse greater levels of violence in certain situations, most notably when they have been insulted or perceived threats to their home or property (Nisbett & Cohen, 1996; see Figure 15.22). Adult southerners show higher levels of anger responses, including greater testosterone and cortisol levels, to threats that northerners might shrug off as inconsequential. Similarly, acts of violence in response to insults or threats to home and property are viewed as more acceptable by southerners. This difference is confined to violent responses of the sort just described, not to violence of all sorts. The culture of honor is sometimes compared with cultures that emphasize "dignity" or "keeping face," with each culture having particular ways of perceiving and reacting to social situations (Leung & Cohen, 2011).

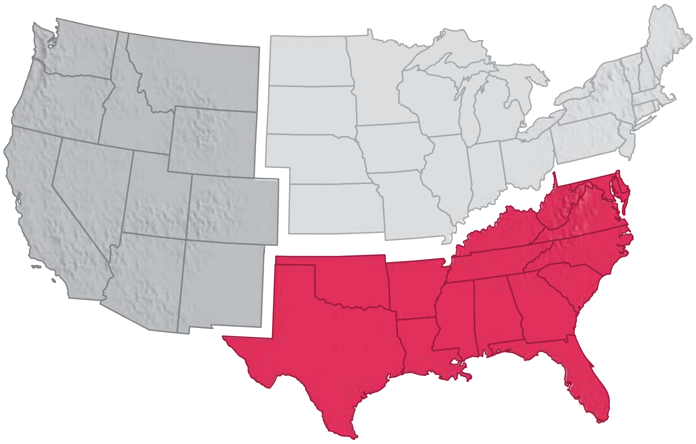

FIGURE 15.22 The culture of honor in the South. Children who are brought up in the southeastern United States tend to adopt a "culture of honor" in which acts of violence in response to insults or threats to property are seen as more acceptable than in other areas of the United States. Similar cultures of honor have been found in other regions of the world where children are socialized in ways that teach accepted forms of response to aggression and insult.

Adherence to this culture of honor seems to take place by middle childhood, and it may be partly learned through different patterns of child rearing in which violent responses to perceived insults are often seen as a legitimate way of socializing children. It may also be mediated by how the culture, parents, and peers shift the social attributional styles of children. Thus, as discussed earlier in this chapter, children vary in the attributions they make about ambiguous situations. Attitudes produced by different cultures may cause group differences in how ambiguous situations are interpreted and what the thresholds are for considering an act as aggressive (Dodge, 2006). These differences can appear very early in development. For example, one study showed behaviors and social categorizations that are typical of a culture of honor appearing earlier and more robustly in young Spanish children than in young Dutch children (Rodriguez Mosquera et al., 2000). Cultures also vary in the extent to which their children are guided toward making either compliant or defiant responses, with the result that different scripts are activated in difficult situations (Chen & French, 2008). Thus, in rural Nepal, children from the high-status Brahman caste are not rebuked for using anger to solve problems in difficult situations, while children from the low-status Tamang caste are strongly discouraged from doing so (Cole et al., 2002, 2006).

Q: What is the "culture of honor"? In what ways might it influence how children from such a culture react in certain situations?

A different cultural contrast discussed earlier in this book (see Chapters 1, 12, and 13) is between collectivist and individualist cultures (Triandis, 1995). Individualist cultures, which include most Western cultures, stress the rights of the individual as the most important consideration in a society. The United States is often said to have one of the most individualist cultures. Collectivist cultures, which exist throughout the world, tend to emphasize the rights of the group relative to those of the individual. It is not simply the case, however, that a particular culture produces only one kind of orientation. When researchers examine parenting styles cross-culturally, they find that both forms of cultural values are taught to young children in all cultures, even if these cultures are normally labeled collectivist or individualist (Wang & Tamis-Lamonda, 2003). But within a particular culture, a child's social status may influence what values are expressed in what contexts. Thus, dominant and powerful members of a culture often find it easier to embrace moral reasoning from an individualist perspective (Turiel, 2002). Moreover, there are also some gender differences in patterns of socialization across cultures, leading to differences in what values are expressed by girls and boys.

Allowing for these variations within cultures as a function of social status and gender, it has still repeatedly been observed that children in individualist societies are strongly socialized to act as individuals who are self-directed and have their own personal styles. Children in collectivist societies are strongly socialized to identify with a group and to think about the common good (Chen & French, 2008). This also seems to be reflected in play. Children from individualist cultures show increased tendencies to engage in "sociodramatic" play, meaning that they tend to act out more fantastical scenarios, often with superheroes or other exotic actors, playing dramatic and unrealistic roles in which they personally save the day. In contrast, children from collectivist cultures tend to act out more mundane, everyday situations that involve family members. Children from these two cultures also tend to resolve conflicts differently. Thus, when groups of four 7-year-olds from China and groups of four 7-year-olds from Canada played with a single highly desirable toy, the Chinese children tended to respond more positively to requests by peers for possession of the toy. Moreover, passive and reticent behaviors were treated with more group acceptance by the Chinese children than by the Canadian children. It was also common for Chinese children to defer to one or two children as group "leaders" who coordinated actions of the group with respect to the toy. Canadian children, on the other hand, referred more to norms of sharing and were more likely to spontaneously give the toy to a peer (French et al., 2011). This study, which had several subtle cultural contrasts, illustrates how in a specific setting and task, cultural differences can manifest themselves in unique and complex ways.

Socialization differences are also seen in parental views of how children should control themselves under stress and how they should handle conflicts with peers. Parents in collectivist cultures are less tolerant of overt conflicts among children, while parents in individualist cultures see merit in some level of disagreement and in defending one's own views. Similarly, parents in collectivist cultures highly value self-regulation skills in difficult situations or conflicts and place a higher priority on the importance of preserving harmony, even if it is at some expense to individual rights (Chen & French, 2008).

These cultural differences have also been interpreted in terms of Bronfenbrenner's ecological systems approach to development, which has been used to interpret many patterns in this chapter (Chen & French, 2008). Children adapt to the niches in which they grow up, finding ways to fit their talents and natures within the culture around them. The dynamic nature of such adaptation is vividly seen in cases where cultures change dramatically over time. One of the first documented instances occurred in the 1930s when the great Soviet psychologist Alexander Luria went to central Asia to study what happened as rural peasants became assimilated into a town and the emerging Soviet culture

(Luria, 1974). Although Luria's investigations largely focused on cognitive factors, they showed how, as peasant children and their parents learned to read, write, and function within Soviet culture, their cognitive styles and ways of interpreting situations began to change and they became better able to fit into the radically changing social structures around them. Later studies have applied this analysis of historical change to the collectivist/individualist contrast. For example, parents in traditional cultures in Turkey shifted away from collectivist ideals to individualist ones concerning their views on child rearing when they moved into cities and became more affluent (Chen & French, 2008). Similarly, as China went through revolutionary changes toward a market economy in the 1990s, researchers found shifts in the traits that parents and peers valued in children. For example, during the early 1990s, childhood traits that were compatible with group harmony, such as shyness, were perceived positively and were related to peer acceptance. But by the end of the decade, those same traits were perceived negatively and associated with peer rejection, as the ability to excel and stand out became increasingly prized (Chen et al., 2005; Chen & French, 2008).

The message of the collectivist/individualist contrast may extend to other supposed contrasts between cultures. Cultures are rarely, if ever, exclusively dedicated to one cognitive style or value system. Instead, most children in most cultures can be thought of as being exposed to most variations. As they grow older, children start to master nuances of how different styles and value systems are likely to be favored in local cultural contexts. Overall, this can amount to broad differences between cultures, but the subtleties and contextually induced variations should always be kept in mind as well (Conry-Murray & Turiel, 2012; Rentfrow et al., 2008).

Q: What are some general ways in which cultures vary in their perspectives of the social world? Are these perspectives better thought of as fixed limitations or as default biases?

Gender Roles and Stereotyping

As we saw in Chapter 14, quite young children are aware of their gender. But how do they learn to map certain activities and objects onto their gender so as to conform to their culture's stereotypes? Although there are arguments that some preferred activities and toys may arise from children's own dispositions, it also seems clear that the culture at large provides considerable information about what it considers to be gender-typical behaviors and preferences. It is thought that children first identify themselves with a gender, then observe what behaviors, preferences, and beliefs are associated with both genders, and then usually adopt the gender behaviors, preferences, and beliefs that are typical of their own gender (Bigler & Liben, 2007; Martin & Halverson, 1981; Ruble & Martin, 1998).

While gender-based toy preferences emerge quite early, at least by 2 years of age (Weinraub et al., 1984), inferences about complex roles and activities take considerably longer to develop, with a majority of children not matching activities to gender until late preschool or early elementary school (Campbell et al., 2004). For example, while a 2-year-old boy might prefer playing with trucks to playing with dolls, not until 4 or 5 years of age might he actually know that certain activities are stereotypically done by boys or girls. Such activities can include hobbies, careers, and even intellectual pursuits, such as mathematics. For example, by second grade, many children, especially boys, see math as an especially appropriate activity for boys (Cvencek et al., 2011). Although these particular stereotypes may vary from culture to culture, it does appear that in all the cultures that were studied, gender-based stereotypes are picked up on at roughly the same time (Knobloch et al., 2005). Thus, the cognitive factors involved in adopting cultural stereotypes involve both universal processes and those that are specific to a particular culture (Kohlberg, 1966).

If cultures can influence perceptions of gender-appropriate activities, can they also affect positive and negative attitudes toward the work typically done by different genders? Unfortunately, there appears to be a widespread effect of how society values different kinds of work associated with different genders, and it seems to be difficult to change. Consider one series of studies looking at how children perceive the relative status of pink- and blue-collar jobs (Liben et al., 2001). Children at ages 6 and 11 years were asked to judge the status of various jobs and their own personal interest in the jobs. First, they were asked to judge familiar jobs, such as doctor, farmer, dentist, plumber, truck driver, auto mechanic, and scientist (culturally masculine jobs), and fashion model, librarian, nurse, secretary, teacher, and bank teller (culturally feminine jobs). Girls and boys at both ages judged the masculine jobs to have a higher status (as measured by questions such as "How hard do you think it is to learn to be a(n) ____?" or "How important is the job of being a(n) ________?"), while saying that they would be more interested in actually doing the jobs that corresponded to the stereotypes associated with their gender.

This pattern of results, however, does not make it clear how the linkage between gender, status, and occupation gets set up in the first place. Perhaps children see the higher status accorded to people in specific jobs and then note the dominant gender. Alternatively, they might form a stereotype that men's work is of higher status, regardless of what it is, simply because it is performed by the "higher-status" gender. To test this second alternative, Liben and her colleagues created novel occupations to which children could not have had any prior exposure and described them to a child either with all males engaging in the occupation or all females, as shown in Figure 15.24. The researchers asked younger and older children the status questions and interest questions. The older children showed a clear gender-linked status rating, judging exactly the same occupation as being of higher status when modeled by males. The younger children showed no significant difference in their ratings based on whether the job was modeled by a male or female; there were no differences in their interest in doing the jobs, and the gender of the children did not influence how they judged the status of the jobs (Liben et al., 2001).

The results suggest that for familiar jobs, gender stereotypes emerge quite early and that jobs typically associated with males are valued more highly. Apparently, this value structure then becomes an interpretive schema for prejudging the status of totally novel occupations as a function of the gender that models that occupation. One obvious question for future research is whether there might be dramatic cross-cultural differences in the extent to which occupations gain or lose status merely as a function of which gender typically holds that kind of job.

One intriguing finding on the emergence of gender stereotypes is that as younger children learn and consolidate a stereotype and before they learn to be more flexible, they may hold stronger stereotypes than older children (Martin & Ruble, 2004). It seems that initially, at around age 3, they struggle to learn a stereotype and that during that period, they apply it unevenly to a sex. Then, when they clearly master the stereotype, they tend to apply it far too rigidly as an essentially all-or-none statement about appropriateness of an activity for males or females. Thus, a 5-year-old might be observed to vehemently insist that police officers can only be men, even if that child has regularly observed female police officers in his neighborhood. This rigidity may be related to an early tendency to see gender roles as closely linked to biological essences (Taylor et al., 2009). As the stereotype is mastered in later childhood and becomes easy to deploy, children tend to become increasingly flexible in the way they use it (see Figure 15.23). Even younger children, however, can show some flexibility when they think about the context in which a gender norm is observed, such as when it occurs in a different culture (Conry-Murray & Turiel, 2012). This may provide ways of helping younger children abandon rigid stereotypes.

The general process of forming group-based stereotypes has been examined within the framework of what is known as **developmental intergroup theory** (Bigler & Liben, 2007). According to this theory, at least as early as age 4, children start to notice perceptually salient group differences and attach these to stereotypes. (This especially happens in regard to "minority groups," groups that are proportionally smaller in an overall population.) The salience of such groups is further enhanced when the culture at large tends to label them, as when a teacher says, "Good morning *boys* and *girls*." Quite remarkably, negative attitudes toward a group can be produced in just a matter of a few weeks. In one study, researchers randomly assigned children as young as 6 to either a blue-colored T-shirt group or a green-colored T-shirt group, and teachers had the children form lines or be seated or do other tasks based on whether they were wearing a blue or green T-shirt. Even though both groups were treated equally, within a few weeks, the children in each group had increased negative attitudes toward the members of the other group (Bigler et al., 1997). If bias can be found in such artificial cases with no real differences in treatment, it is easy to see how much stronger the effects can be in the real world. Later studies have shown that 5-year-olds will quickly adopt negative biases to an out-group that is set up on clearly arbitrary grounds and will distort information so that it is positively construed for the in-group and negatively construed for the out-group (Dunham et al., 2011; see Scientific Method box). More naturalistically, even preschoolers show group favoritism at an implicit level that is just as strong as it is in later childhood and adulthood. The preschool children seem to be "prepared" to develop such implicit prejudices and to quickly adopt them at full strength (Dunham et al., 2013).

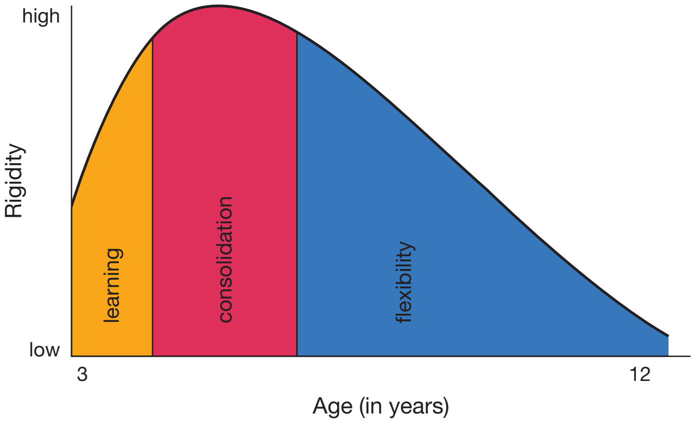

FIGURE 15.23 **Gender stereotype rigidity and age.** The rigidity of gender stereotypes, as learned from a culture, reaches a peak at roughly 5 years of age. Adapted from Martin & Ruble (2004).

Biases can also emerge from other superficial markers of out-group status, such as accent. For example, when two novel speakers were observed by 2-year-olds, both U.S. and French children preferred to give a "present" to the individual who was a native speaker as opposed to giving it to someone who was speaking with a foreign accent (Kinzler et al., 2012). Even younger infants (10-month-olds) preferred toys that were modeled by people with native accents as opposed to foreign accents. Children also preferred to associate with those who had their same native accent (Kinzler et al., 2009).

The use of stereotypes to predict the behaviors of others does not require a rich sense of the mental lives of others, which is part of the reason stereotypes are so pernicious.

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

The Development of Racial and Ethnic Occupational Stereotypes

For many years, it has been known that prejudice against disadvantaged ethnic and racial groups is present by at least the elementary school years (Clark, 1955). The nature of prejudice and discrimination has changed in the past few decades, however, from explicit and willful attacks on other groups to more implicit forms of discrimination in which the actor often believes that he is not prejudiced (Dovidio et al, 1997; Fazio & Olson, 2003; Wittenbrink et al., 1997). Interestingly, the attitudes of parents and peers do not always predict those of children (Aboud & Doyle, 1996; Stephan, 1999). Children seem to be most influenced by those peers and adults whom they most respect and who discuss prejudice in ways that touch on topics that the children care most about (Aboud & Fenwick, 1999). In addition, some forms of prejudice may arise from observations of how the culture at large seems to treat and value different groups. In the United States, it has repeatedly been shown that both European-American and African-American children tend to develop negative stereotypes regarding African Americans (Aboud, 1988; Spencer & Markstrom-Adams, 1990), assuming that positive traits, such as being intelligent or nice, are more likely to be seen in European Americans and that negative traits are more likely to be seen in African Americans.

One line of work asks how children's views of occupations might be influenced by these ethnic and racial stereotypes (Bigler et al., 2003). This research follows the same approach as that used in studies of gender stereotypes and children's evaluations of occupations (Liben et al., 2001). African-American children from the first and sixth grades and from higher and lower socioeconomic status (SES) groups were asked about the status of familiar and novel occupations and also about their interest in engaging in those jobs themselves. For the familiar jobs, even the first-graders had already learned from their culture stereotypes about the relation of job status to the dominant ethnic and racial groups, assuming that European Americans were more likely to dominate in the higher-status jobs and African Americans in the lower-status jobs. This difference was just as strong in African-American children whose parents were from high-SES backgrounds and thus occupied high-status jobs. Evidently, counterexamples from their own family were not sufficient to block the cultural stereotype. At the same time, and contrary to gender results, the children all indicated a preference to have the higher-status jobs, even though they perceived such jobs as being dominated by a racial group different from their own.

The most compelling result, however, came in a study modeled closely after the gender study described in Figure 15.24. Novel occupations were pictured with either European-American models or African-American models doing the same jobs. For exactly the same occupation, the race of the models had a large impact on status ratings by both first- and sixth-graders, with the occupation being granted higher status when modeled by European Americans. The children also tended to show a tendency to have a greater interest in pursuing a job when it was modeled by European Americans. This result has been echoed by other findings, including the finding that children in South Africa tend to associate racial groups with social class (Olson et al., 2012).

This constellation of results illustrates the challenges of reducing stereotypes about occupations and roles and reducing the use of those stereotypes to drive prejudices about types of peoples. Sadly, it seems that even if an underprivileged group makes great strides by moving into a profession previously populated by a dominant group, unless those strides are made in many fields at the same time, those advances may be undercut by a reduction of the perceived status of the profession.

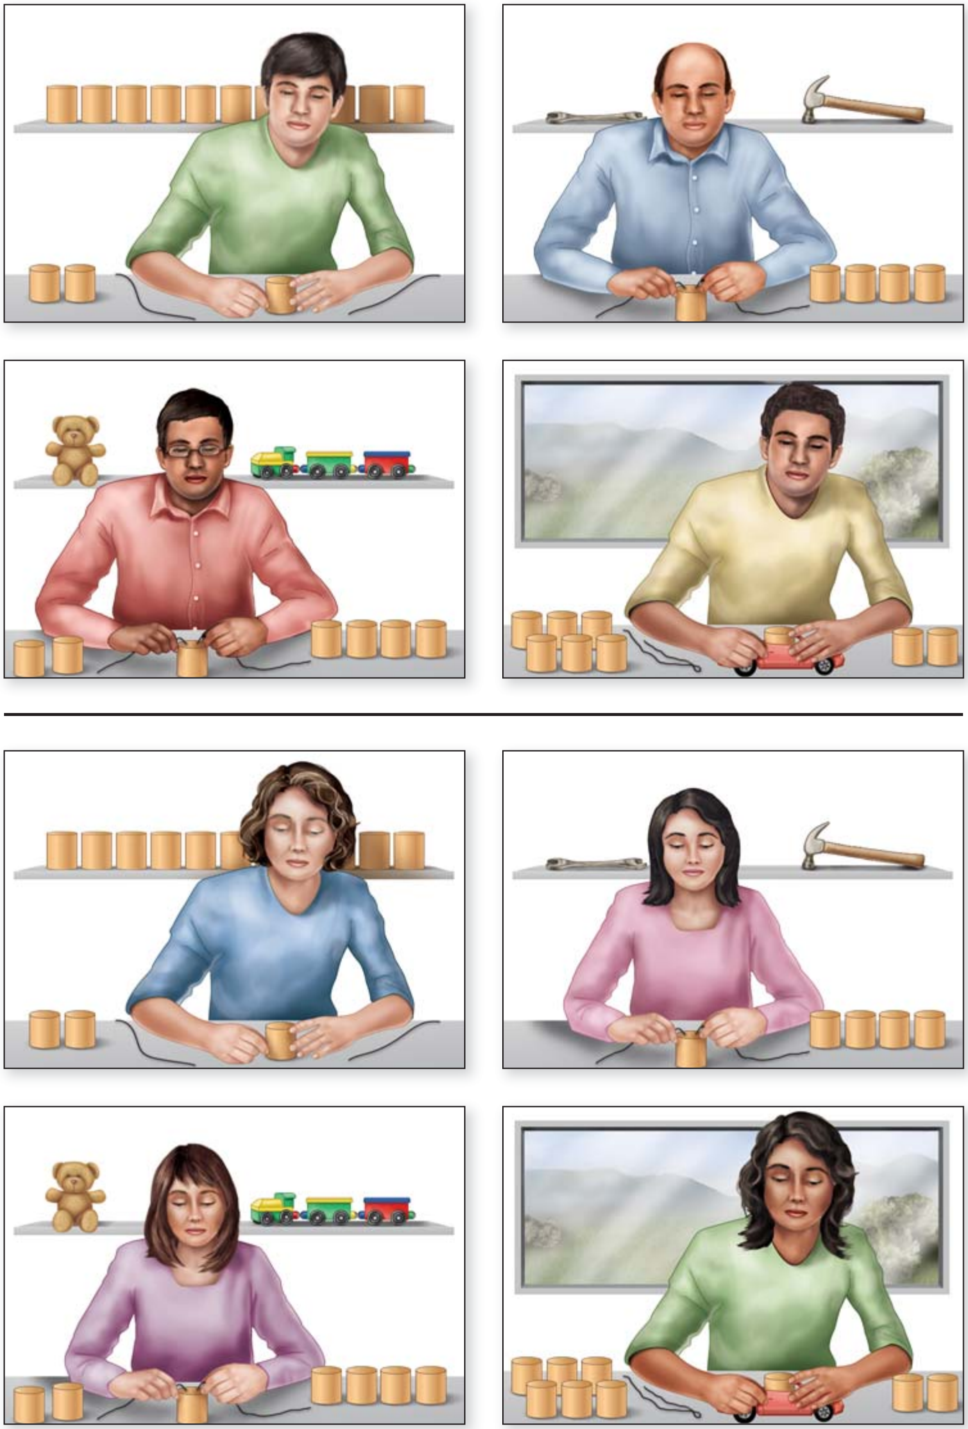

FIGURE 15.24 **Job status and gender.** Illustrations based on a study in which a novel occupation (here called "a clipster") was described to children with either all-male or all-female workers. At age 11, children accorded the same job much higher status when it was modeled by males. Adapted from Liben et al. (2001).

SCIENTIFIC METHOD: Effects of “Minimal” Group Affiliations

Hypothesis:

By age 5, assignment to a clearly arbitrary group can cause immediate biases against members of another group.

Method:

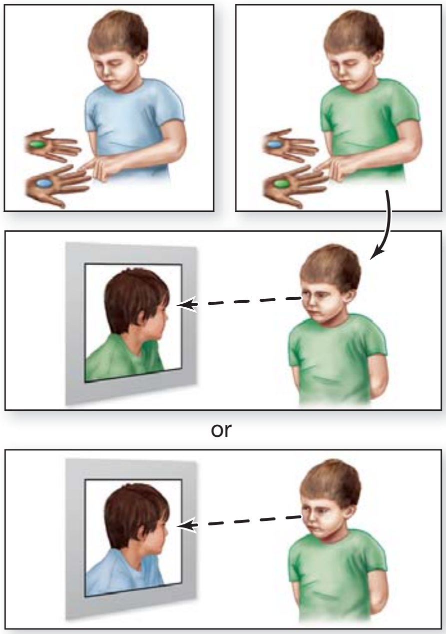
1. Sixty-four 5- and 6-year-olds were randomly assigned either to a group that wore green T-shirts or to a group that wore blue T-shirts, with assignment based on the children choosing a coin from the experimenter’s closed hand.
2. Children heard one story about a child in a picture who wore the same-colored T-shirt as the participant and another story about a child who wore the other-colored shirt. Both stories assigned an equal number of positive and negative behaviors to the child in the picture (four each).
3. All children were asked to recall details of the stories and to choose which child protagonist they wanted to play with.
4. Researchers coded memory of positive and negative behaviors and playmate choice.

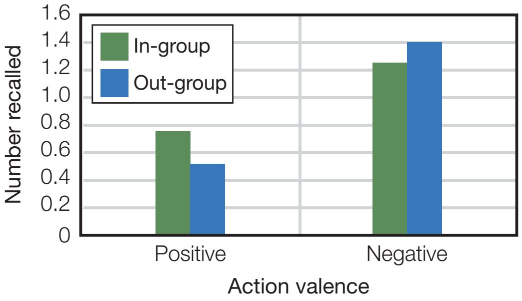
Results:

Participants recalled significantly more positive behaviors about in-group characters than about out-group characters and showed a tendency to recall more negative behaviors about out-group characters. They also strongly preferred in-group characters as potential playmates.

Conclusion:

Even though membership in the group was clearly arbitrary, children as young as 5 processed information differently about characters that matched their in-group versus those in an out-group.





Source study: Dunham et al. (2011).

We only need to associate negative behaviors with a certain group to predict how they will behave. Those predictions may be more wrong than right, but they are often made in cases of racist and gender-based stereotypes. Because we do not need to take into account another’s beliefs and desires when using a stereotype to predict behavior, even individuals with autism can use stereotypes even though they are unable to pass traditional theory of mind tasks (Hirschfeld et al., 2007). It could be that sophisticated insight into another person’s mind would lead to empathy and thereby blunt the bias. But unfortunately, sophisticated insight into other minds does not guarantee open-mindedness toward other groups. In fact, in one study, elementary school children who were less egocentric and more aware of how an out-group’s preferences might differ from their own also showed more negative bias toward those out-groups. Apparently, having additional information on how the two groups potentially differed enabled children to build up stronger reasons for their biases (Abrams, 2011).

As children begin to enter middle school, they start to realize the inappropriateness of holding negative stereotypes. This emerging awareness can in some cases cause older children to do worse than younger children on tasks that would be most easily solved by explicitly acknowledging race. For example, when 8- and 9-year-olds were shown pictures of 40 faces that varied on several dimensions, including race, and had to guess which one the experimenter had in mind, they solved the task more quickly and with fewer questions than 10- and 11-year-olds (Apfelbaum et al., 2008). The older children were more reluctant to use explicit references to race to solve the task even when it would clearly have helped them to do so, whereas the younger children were relatively oblivious to the social discomfort of talking about others in terms of their race.

Parental behavior is related to racial bias in their children, but perhaps not in ways that you might think at first. For example, one study of European-American mothers and their children found that virtually all the mothers in the study used "color-blind" language in reading race-themed books to their children, and thus the way they referred to other races in that context did not predict racial bias in the children. However, those children whose mothers had a higher proportion of non-European-American friends showed considerably less racial bias than those children whose mothers had fewer non-European-American friends (Pahlke et al., 2012). Apparently, children are more influenced by their parents' actual relationships with people from other ethnic groups than by how they talk about them.

Q: Describe some parallels and differences in the development of gender and racial stereotypes.

Conclusions

The child's life outside of the family clearly matters. At times in development, the influences of peers can be truly dramatic and can seem to overwhelm the influence of parents. In addition, the culture at large, through its media and simply through daily encounters with its rituals, institutions, and workers, communicates a host of beliefs, attitudes, and stereotypes to young children. For the most part, these influences are implicit, occurring outside of awareness; indeed, those who hold certain prejudices and stereotypes are often shocked when those mental views are revealed to them. The cognitive components of social interactions and of cultural influences remain a largely unexplored area but one that is gaining a great deal of attention in recent research. The challenge for the future is to integrate these cognitive components with the social and motivational factors that govern the interactions between children, their peers, and their larger culture. Many of these issues can also be fruitfully informed by taking a social ecological perspective on development in which we ask how children end up fitting into social ecosystems.

Although all areas of developmental psychology must confront the tradeoffs between naturalistic observational studies and experimental paradigms, this dilemma is especially vivid in studies of how larger communities influence a child's development. Whether the research is focusing on the media, cultural groups, or peers, the difficulty of making random assignments to experimental designs can pose a special challenge for making unambiguous causal conclusions. Thus, it can be difficult to truly randomly assign children to groups that experience different kinds of media in different ways or that are immersed in different kinds of peer relationships. Almost always, other factors—including the child's own disposition and background environment—are also involved in whether a child is in one situation or another.

Moreoever, the rapid rise of Internet communities, social network sites, and new forms of communication, such as texting, all raise questions about how these new forms of relationships might have qualitatively different kinds of influences on children. It is too soon to tell whether an increasingly wired world really will change the nature of social and cognitive development or whether developmental patterns will remain robust across these dramatic technological changes. The only way to know is to constantly conduct well-designed studies that track each new technology and its possible influences. We also see that these new social technologies and the rich trails of interactional data that they leave behind can lead to new forms of analysis, such as the rapidly growing formal and computational studies of social network effects. Without such tools, we might never have known the extent to which individuals we have never met, but who are three friendship links away from us, may influence our health, our values, and our lifestyles.

STUDY AND REVIEW

SUMMARY

Levels of Affiliation

- Children grow up in several levels of communities, starting with their own families, then moving on to peers, local subcultures, and finally the culture at large in which they live.
- Peers have a critical influence, especially in middle childhood and early adolescence. Indeed, some have argued that, as humans mature, they have an evolutionary bias to attend more to peers than to parents.
- Peer relations can be thought of as occurring at three levels: interactions, relationships, and groups.
- Interactions are the simplest forms of relations, ones that may well be transient. In younger children and infants, interactions may be little more than mutual arousal of excitement or distress. Older children show notions of reciprocity and sharing and start to engage in play and pretense.
- Relationships are unique and repeated patterns of interactions between two people, such as a child's relationships with peers, parents, or siblings. Infant relationships may include strong bonds of affection and expectations of classes of behaviors, but they do not contain the reciprocal give-and-take found in toddlers and older children and which is so essential to friendships. As children approach and enter adolescence, friendships take on more intensity, and gender differences in friendship patterns become more prominent.
- In addition to real friends, many children also have imaginary companions. They may also have enemies. Children also can become involved in bully-victim relationships. Bullies often have an inflated sense of self-esteem rather than low self-esteem, contrary to popular lore. The victims of bullies tend to be repeated targets of bullying who suffer considerably from the experience.
- While friends and even imaginary companions are usually associated with positive outcomes, enemies and both parties in bully-victim relationships are associated with negative outcomes.
- Because the formation of groups may require somewhat more cognitive complexity, groups are not voluntarily formed by human infants. Preschoolers form ad hoc groups, but in elementary school, children start to form groups that are more stable, often exclusive cliques.
- Sociometric status is a measure of a child's standing in a group. It is usually measured by asking peers which children in the relevant group are the most liked and which ones are the least liked. There seem to be five different kinds of children as revealed by such ratings: popular children, rejected children, controversial children, average children, and neglected children. The most negative developmental outcomes are associated with rejected children, who are the most heavily studied group as well.

Media Influences on Development

- As a person moves beyond peers to the larger culture, one of the most powerful influences worldwide is that of television, which has become a major part of the daily lives of people, not just in the developed world but also in the developing world. Many children in developed countries spend more time watching television than doing any other activity, including time spent learning in school.
- While infants may not be influenced much by the content of television, by 2 years or so, children start to become engrossed with the content of television that is age appropriate.
- Educational programming has been shown to have both positive cognitive and positive social effects on children. Unfortunately, it is not the most frequently watched form of television.
- Entertainment television tends to contain high levels of violence, levels that have remained equally high for decades. The vast majority of research on the influences of television on children has focused on the question of whether violence on television leads to aggression in children. Across several hundred studies, both of a naturalistic and experimental nature, it is clear that exposure to violent programming is correlated with higher levels of aggression and probably causes it.
- The correlation between violent television watching and aggression is not massive, and it is certainly not able to predict a high likelihood of aggression by any child based on her viewing habits, but when taken for a population as a whole, the risk of increased aggression as a result of viewing violent television may represent a health hazard of a magnitude close to that of the relation between smoking and lung cancer. It has been difficult to address this potential health problem through public policy. A large array of other potential effects of television is increasingly receiving attention.
- As computers become ever more prevalent in the home and video games become more complex, comparable questions have arisen about their influences. Although a smaller number of studies have been conducted in this area, the effects appear to be similar to those produced by television, at least in the area of violence. Nonetheless, positive cognitive benefits can be found for educational video games, and even prosocial effects may be found for the right kinds of games.

- As interactive technologies improve on the Internet, the very nature of social interactions may be shifting as well and may reflect a new form of cultural socialization of children. Internet communities can have positive influences when they serve to maintain and enhance relationships that started and continue in the real world. There is greater concern about relationships that start on the Internet.
- One worrisome new trend is the occurrence of bully-victim relationships on the Internet, often known as "cyberbullying." Cyberbullying may be more severe than real-world bullying because it can occur more easily without adult monitoring and has the potential to put vulnerable children into painful circumstances with much larger audiences.

Roles in the Larger Culture

- Cultures as a whole can also convey styles of thought and kinds of roles that the actors may never explicitly know that they play. These may include a culture of honor in the American South and different attitudes in individualist and collectivist cultures. The most reasonable view of all these effects may be that most people in most cultures have access to several of these roles and cognitive styles, but use them to different extents in different contexts.
- Distinctive roles for the two sexes can also be communicated by cultures, not just in terms of favorite toys, but in terms of expectations about gender-appropriate occupations and hobbies. Those expectations are abstracted from familiar instances, allowing generalizations about novel instances in which men and women are seen as more likely to be in certain occupations.
- Just as there is gender stereotyping, there is also racial stereotyping. Racial stereotypes are typically first seen in young schoolchildren and become stronger during the elementary school years even as older children become better at masking overt bias. There are strong tendencies to build negative impressions of out-groups that can easily fuel racial and ethnic stereotypes and biases.

THOUGHT QUESTIONS

1. Imagine that you are a principal of a high school in a diverse but fairly affluent community. The PTA comes to you with concerns about controlling the content of the student-run high school newspaper. What regulations would you put in place, and how would you justify them to the students?
2. Children often tease each other in ways that are playful forms of affection. Yet, other forms of teasing can be highly destructive and can even be considered bullying. Is it feasible to develop an intervention program for children that could sanction playful teasing but stop harmful teasing, or is it better to try to stop all forms of teasing?
3. Many middle schoolers and young high schoolers spend countless hours texting to each other when it is equally possible to talk on a phone or even chat face-to-face. What factors motivate this preference for texting, and how might these factors change during the high school and college years?
4. It has been argued that extensive use of social networking sites can lower children's self-esteem as they encounter inflated, sculpted, and unrealistically positive portrayals of peers and feel that they are inferior in comparison. Consider whether this claim is plausible and whether children might be much more at risk to such influences than young adults.

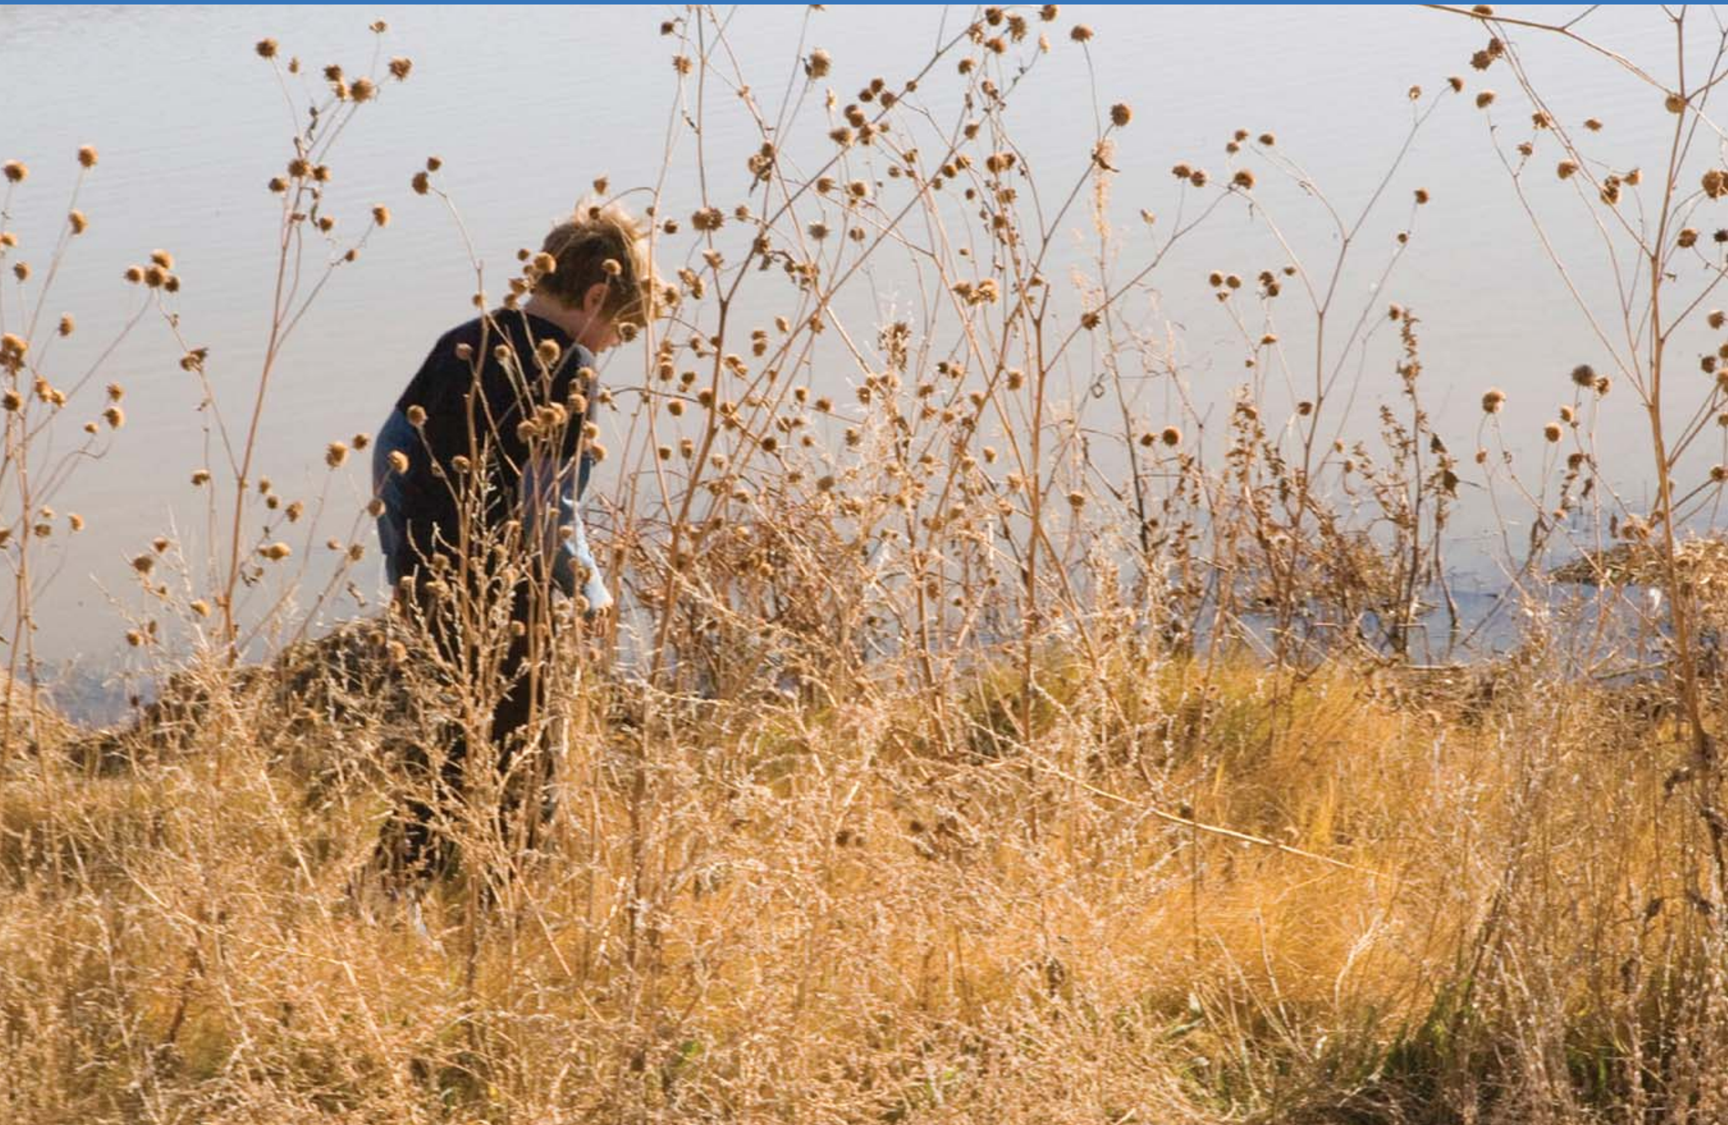
Conclusions

Summary



Sometimes parents have dramatically different outcomes with their children, despite treating them very similarly. Imagine a family with two boys, Adam and Bill, who are fraternal twins. Born at the same time and seemingly experiencing pretty much the same childhoods, they nonetheless take very different trajectories. Adam is an easygoing child who develops along a normal path in virtually all respects. He is a popular, outgoing boy who does somewhat above average in school and enjoys a wide variety of extracurricular activities. In high school, he dates frequently, plays second-string quarterback on the football team, and does well enough to be admitted to one of the regional state universities.

Bill is not an easygoing child, and he seems to gradually decline into his own private hell. His parents do not remember anything unusual about his infancy, but by the time he is in preschool, problems start to emerge. Bill is told that it is important to wash his hands before eating or else he might ingest germs. Very soon, hand washing becomes a dominant part of his life. He washes his hands dozens of times a day, often for more than 30 minutes at a time. His hands are bright red and cracked and sometimes bleed. His parents tell him that the washing is excessive, and at one level he seems to recognize the problem, but he cannot seem to help himself.

As he grows older, Bill's problems compound themselves. He continues to wash obsessively, but now he also spends excessive time in the bathroom wiping himself, usually with the result of completely filling the toilet bowl with toilet tissue. His parents give him a house key when he is 12 so that he can enter and leave the house when they are not home. Soon he finds himself going back to the house as much as a dozen times to make absolutely sure that he has really locked the door. Often, after checking that the door is locked, he rushes into the house to make sure he hasn't left the faucet running, which in turn might trigger another bout of hand washing. As Bill cycles through these routines, he is often late for school.

Bill's problems continue to plague him throughout his life. His parents try a wide variety of therapies to little avail, often because they don't seem to be designed for children. For example, his parents put him on medications to reduce his symptoms, but there is no evidence that the medications are safe when used by children. As an adult, Bill takes a medication that helps control his rituals, but the side effects are aversive, creating a constant battle between the effects of the medication and those of the disease.

This example raises several questions that frame much of this chapter. What sorts of psychological problems commonly afflict children and adolescents? What are the distinguishing features of such problems and what are their causes? Finally, how do developmental issues affect these psychological disorders? Is it even meaningful to use the same label to classify a mental illness in a 7-year-old child and in a 37-year-old adult? More broadly, all of these questions relate to the question of what counts as psychopathology and how those criteria might change with age. In most cases, psychopathology is considered present when an individual reveals behaviors, thoughts, or emotions that are unusual and that make it difficult for the individual to function or that cause difficulties for others (Nolen-Hoeksema, 2011). Psychopathology can manifest itself in the despair of depression, the disabling feelings of anxiety, or the disordered thoughts of a person with schizophrenia. In all disorders, however, we have to keep in mind that deviance at one age may not be deviance at a younger age. We may think that an adult who throws tantrums by dropping down on his stomach and pounding on the floor of a supermarket is severely emotionally disabled, but we may accept such behaviors as within the range of normal for a toddler. Thus, it is important to put behaviors in a developmental context when considering whether they are likely indications of psychopathology. Psychopathology from a developmental perspective therefore poses several unique challenges. First, we need to reinterpret behaviors in terms of whether they are symptoms of psychopathology. Second, we need to ask if some forms of psychopathology require a certain level of psychological development to manifest themselves. For example, the forms of depression that seem to be driven by ruminative cognitions (repeated thoughts that won't go away) might not be present in young children. Third, there is the challenge of knowing how to treat psychopathology when it is present. For example, will therapies designed around a certain form of self-awareness or "mindfulness" be effective in a kindergartener?

In this chapter, we will consider several mental and behavioral disorders, starting with those that tend to emerge earliest in development and progressing to those with the latest typical age of onset: autism, anxiety disorders, obsessive-compulsive disorder, eating disorders, mood disorders, conduct disorders, and schizophrenia. As we work through these disorders, we will revisit the questions just raised and see how the answers vary across different types of disorders. Finally, we will consider how clinicians treat these problems and how the science of developmental psychology, as discussed in earlier chapters of this book, contributes to a better understanding of the disorders.

Q: What are some general questions that arise in considering psychopathology in children?

Autism

Some children seem to have severe problems in socially interacting and communicating with others (autism) or substantial problems in social intelligence (Asperger's syndrome). In Chapter 13, we mentioned that autism may provide evidence for a theory of mind module that may be defective, perhaps for genetic reasons, in people with autism and Asperger's. Behaviorally, however, autism is associated with a wide range of other problems as well. In the clinical psychology literature, disorders in which such a broad spectrum of problems occurs have often been called **pervasive developmental disorders**, presumably because they affect so many aspects of a person's life.

Features of Autism

Autism was first diagnosed by Leo Kanner in the 1940s (Kanner, 1943), when it was often known as Kanner's syndrome. Before Kanner's work, individuals with autism were often lumped together with children who were labeled "retarded." Kanner noticed a set of problems that occur together and that are now considered the central features of autism: emotional aloneness or remoteness, obsessions with preservation of sameness, and a tendency toward **elective mutism**, in which children capable of speaking seem to have no desire to do so, especially in a communicative manner. Children diagnosed with autism can range from those who show massive cognitive deficits in all areas and require assistance with even the simplest daily functions to those who, in rare cases, can exhibit remarkable skills in specific areas. For that reason, any description of the features of autism must be understood as only approximate for a given child with that diagnosis. Indeed, it is common to talk of "autism spectrum disorders" so as to make clear how much the various deficits and atypical behaviors can vary (Klin et al., 2004; Lord & Jones, 2012; Rapin & Tuchman, 2008a; Volkmar et al., 2007). For the same reason, most current researchers tend to think that there is not just one cause of autism and that, instead, different kinds of "autisms" may arise through different causal pathways (Betancur, 2011; Rapin & Tuchman, 2008b).

One set of symptoms revolves around problems with social skills. Children with autism may not respond to social overtures by others. For example, they may not respond when spoken to, sometimes even if their own name is called. They often seem to lack empathy for others (see Chapter 12) and seem to have trouble understanding the mental states of others, such as their beliefs or feelings (Rapin & Tuchman, 2008a; Volkmar et al., 2007). A related set of problems concerns difficulties in "reading faces." One sign of this is shown in the very different ways in which people with autism scan faces during a social interaction. Most people keep referring back to another person's eyes as the most significant source of social information, but people with autism often seem to focus primarily on the mouth (perhaps because it moves the most) or even on other salient objects in the environment, such as a moving hand. Figure 16.1 shows how eye-scanning patterns in toddlers with autism differ from the patterns seen in typically developing toddlers.

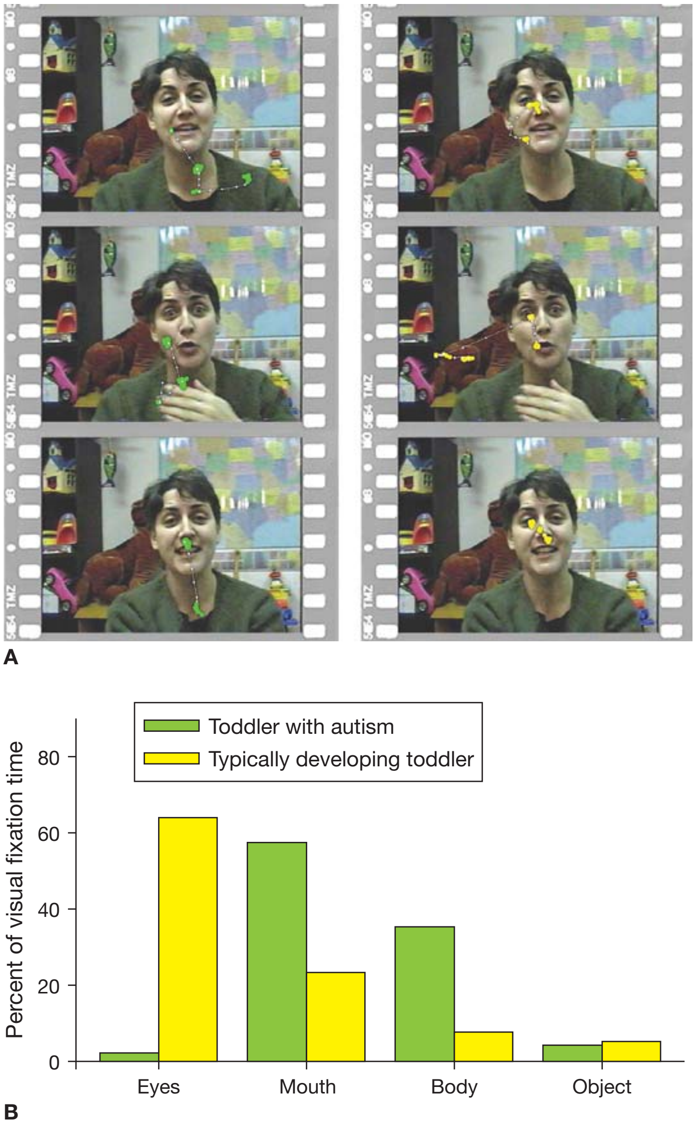


FIGURE 16.1 Visual fixations by toddlers with autism and toddlers without autism. Toddlers with autism and typically developing toddlers watched a video of an adult, and researchers tracked where the toddlers directed their eyes. **(A)** Stills of the video indicate the eye scan patterns and show striking differences between the scans of typically developing toddlers (in yellow) and the scans of toddlers with autism (in green). Note in particular how typically developing toddlers focus on the eyes to a vastly greater extent. **(B)** The graph shows the percent of visual fixation time on different body parts by the toddler with autism and the normally developing toddler. Adapted from Jones et al. (2008).

A second set of symptoms revolves around language and communication skills. Children with autism frequently show significant delays in the emergence of language, sometimes never acquiring language at all. Even when they do have some language, they may have difficulty with such linguistic devices as irony. They may also engage in *echolalic speech*, in which they repeat back the words and phrases of others verbatim or repeat certain set scripts. Above and beyond language deficits, they may also show communicative difficulties when engaging in or understanding such activities as pretend play (Rapin & Tuchman, 2008a; Volkmar et al., 2007). They also may show difficulties in adjusting their gaze appropriately in communicative tasks involving pointing and gesturing, often taking an excessively long time to shift their gaze (Falck-Ytter et al., 2012).

A final set of symptoms involves stereotyped movements that are often repeated many times, such as a particular manner of waving the hands. Children with autism may show such repetitive movements and marked resistance to any change in routine as well as a tendency to make the world orderly in ways that other children do not, such as sorting all the toys in a room by color. They may also focus on an extremely narrow area of interest, such as having a particular fascination with airplanes. And they may sometimes show rigidity and perseveration—that is, the continuing repetition of a behavior over an extended period of time (Leekam et al., 2011; Rapin & Tuchman, 2008a; Volkmar et al., 2007).

Diagnosis of Autism

Although the age of onset of autism remains unclear, the first diagnoses typically are made no earlier than about 18 months of age, often in association with language delays. There are some suggestions that even in infancy, autistic children do not connect well socially to their caregivers, leading researchers to wonder whether it might be possible to base a diagnosis on symptoms that are present even before language delays are evident (Barbaro & Dissamayke, 2009; Macari et al., 2012; Yirmiya & Charman, 2010). But the low incidence of autism makes it very difficult to collect enough data to support firm conclusions about symptoms in the first few months of life. (After a child is diagnosed with autism, retrospective reports from caregivers can be colored by their current perceptions of the child, making such reports less useful than observational data gathered before a problem is suspected.) One recent strategy involves **baby sib studies**. Such studies are based on the finding that younger siblings of children with autism are at far greater risk for the disorder themselves, presumably because of shared genetic risk factors. Researchers are therefore starting to intensively study younger siblings from early infancy on the assumption that some percentage of the siblings will develop full-fledged autism and possibly reveal early precursor behaviors. It is still too early to know what the full set of precursor behaviors might be, but there are indications of some subtle problems with social engagement during the first year of life (Caronna et al., 2008; Macari et al., 2012). At 1 year, there seem to be delays in early language skills, ranging from difficulties in joint attention (the ability to understand a social interaction in which both parties are meant to attend to the same thing; see Chapter 6) to delays in babbling.

Another method for investigating early signs of autism relies on parents' videotapes of their children's earliest birthday parties, which can give researchers a window into a child's social interactions as early as 1 year of age. In one such study, judges used birthday party videos to score 20 children later diagnosed with autism and 20 children who were not later diagnosed with autism on various communicative measures, including the degree to which they responded when called by name and the extent to which they seemed to engage in joint attention. The judges who scored the children's behaviors in the videos were not informed about which children were later diagnosed with autism, but they found less social interaction, less joint attention, and less responsiveness to their own name in the children who were later diagnosed with autism (Osterling et al., 2002). Researchers who watched videotapes of infants in other situations (not birthday parties) claim to have found anomalies in gaze and affect perhaps as early as 6 months in infants who would later develop autism (Clifford & Dissanayake, 2008). Even so, these results pertain to older infants, and it remains much less clear whether signs of autism are already present in the first few months of life.

Incidence of Autism

Autism was initially reported to occur in roughly 3 to 5 out of every 10,000 children. But the incidence has been reported to be rising, with some studies finding rates as high as 1 per 150 children, and over 1 per 100 children when the less severe Asperger's disorder is also included (Elsabbagh et al., 2012; Fombonne et al., 2011; Rapin & Tuchman, 2008b). Some prenatal factors (such as viruses or maternal illnesses or substance abuse or environmental toxins) or some postnatal environmental experiences may account for some of the increase in autism (Kaye et al., 2001; Taylor et al., 1999). But most of the increase is probably illusory and reflects more extensive screening in all social groups and more accurate diagnosis as well as diagnosis at earlier ages (Rapin & Tuchman, 2008b).

There has been some recent controversy as well over whether autism is overdiagnosed as a result of other cognitive and social disabilities being swept into the category inappropriately. This controversy crystallized around the revision of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), the manual used by clinical psychologists and psychiatrists to diagnose mental disorders. In May 2013, the DSM-V revision replaced prior versions that had appeared in 1994 (DSM-IV) and 2000 (DSM-IV-TR). DSM-V listed the same diagnostic features of autism as earlier manuals, but it increased the strictness of the diagnostic criteria (for example, requiring more symptoms for a diagnosis), which may result in the exclusion of less severe cases. As part of the changes, it also combined autistic disorder, Asperger's disorder, childhood disintegrative disorder, and pervasive developmental disorder not otherwise specified (PDD-NOS) into one larger category called autism spectrum disorder, or ASD, arguing that the divisions into four related disorders had been artificial and that the disorders occurred in more of a continuum. It is not yet clear how much the changes will affect the number of diagnosed cases of autism, but some researchers project quite substantial drops in those receiving ASD diagnoses, especially among those who were formerly diagnosed with Asperger's or PDD-NOS (McPartland et al., 2012). More generally, however, the shifting boundary of criteria for diagnosis with ASD is not likely to influence psychological theories of autism as much as debates about availability of resources for people with disabilities and conclusions as to whether there is a true "autism epidemic."

Autism is diagnosed four times as frequently in boys as in girls. This is a pronounced sex difference, but this kind of disparity is not unusual for incidences of mental illness. The difference may be even larger for milder cases of autism, such as Asperger's disorder, which has been reported to have a male to female ratio of 8:1 (Auyeung & Baron-Cohen, 2008). One hypothesis aimed at explaining why autism is more common in boys suggests that the psychological features of autism resemble an extreme version of the male social brain (Baron-Cohen, 2003; Baron-Cohen et al., 2005). According to this theory, the sexes have different ways of viewing the social world, which can be imagined as opposite ends of a continuum. In particular, females are said to be more sensitive to emotional and mental states in others and to be more skilled socially and more empathic, while males have a tendency to be less socially aware, empathic, and adroit and to also have more of a tendency to analyze and systematize objects and events (Lai et al., 2012). The ability to systematize is more explicitly defined as "the drive to analyze a system in terms of the rules that govern the system, in order to predict the system" (Baron-Cohen et al., 2005, p. 820).

Causal Factors

As we have noted, autism has been hypothesized to involve a severe impairment of the ability to empathize and the related ability to "read" others by engaging in theory of mind reasoning (see Chapter 13). At the neural level, some fMRI studies have suggested that individuals with autism show less activity in brain regions associated with social cognition (Philip et al., 2012). The theory suggests that without these social skills, people with autism tend to rely on other more analytical and systematized ways of understanding, which is an extreme form of the usual male analytical tendency. This observation also fits with the tendency for many individuals with autism to have an intense interest in orderly routines, arrangements of objects, and the like. It may also explain why autism has been found to be more common in families of physicists, engineers, and mathematicians, groups that tend to represent stereotypical male cognitive styles (Baron-Cohen et al., 1998). Yet, it is not clear how such sex differences are affected by biological mechanisms—that is, how the presence of a Y chromosome could lead to behavioral differences related to autism. There are some indications of links of subsequent autistic traits (such as reduced eye contact, less empathy, and more systematizing) to fetal testosterone levels (see Figure 16.2). Higher levels of fetal testosterone in either sex are correlated with reduced social skills and increased systematizing tendencies (Auyeung & Baron-Cohen, 2008; Auyeung et al., 2009, 2010; Mills et al., 2007). Normally, of course, higher fetal testosterone levels are much more common in males. Somewhat more surprisingly, even in adults, testosterone can have an influence on empathy-related brain regions that presumably had been influenced prenatally by sex hormones. Thus, when

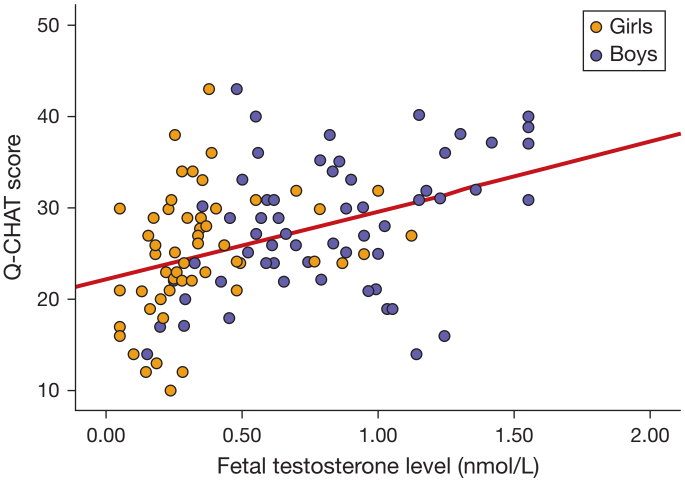

FIGURE 16.2 Fetal testosterone and subsequent autism. For both boys and girls, there is a significant positive relationship between the amount of fetal testosterone and later diagnosis of autism-related symptoms. On the graph, the y-axis is a measure of degree of autism symptoms, known as Q-CHAT (Quantitative CHecklist for Autism in Toddlers), in which higher scores represent more symptoms. The x-axis depicts the amount of fetal testosterone as measured in the mother's amniotic fluid. Higher levels of testosterone are related to higher Q-CHAT scores, especially in boys. Adapted from Auyeung et al. (2010).

adult women are given low doses of testosterone, they experience temporary impairments in their ability to perform on subtle empathy tasks (van Honk et al., 2011). Such effects of testosterone and other hormones on social-emotional states, however, are complex and often only occur in specific contexts (Bos et al., 2012).

Q: What is the sex difference with respect to the incidence of autism, and what is an explanation for this difference?

Another biological explanation for autism focuses on the genes. While there is substantial evidence for a genetic predisposition to autism, the specific genetic influences are complex, involving several distinct gene locations and intricate patterns of gene interactions (Devlin & Scherer, 2012; Folstein & Rosen-Sheidley, 2001; Freitag, 2007; Geschwind, 2008; Hu, 2013; State & Levitt, 2011). Nonetheless, the rates of autism in monozygotic and dizygotic twins provide a clear illustration of a genetic influence at work (Geschwind & Spence, 2008). Each member of a pair of monozygotic twins is substantially more likely to have autism if the other twin has the disorder. One study that used fairly strict diagnostic criteria found a concordance rate (the likelihood that two individuals share the same trait) among monozygotic twins of roughly 60 percent, with a concordance of roughly 20 percent among dizygotic twins. If the diagnostic criteria are broadened to include a spectrum of cognitive and social abnormalities, the concordance is almost 80 percent for monozygotic twins and roughly 30 percent for dizygotic twins (Hallmayer et al., 2011). In a related study, researchers gave a difficult theory of mind task both to siblings of people with Asperger's disorder and to a control group of nonrelatives. They found higher concordance rates for difficulty in understanding others' states of mind among the siblings than among the nonrelatives (Dorris et al., 2004).

Genetic influences for autism may also arise as a result of mutations to the mother's eggs or the father's sperm later in the parent's life. The risk of some disorders, such as Down syndrome, are related to the mother's age, and maternal age was often thought to be more associated with the development of most disorders in the child than paternal age. This is because the same set of eggs is present throughout much of the mother's life and has more time to accumulate mutations than sperm cells, which are constantly being produced. Yet, some researchers have suggested that the age of the father may be related to the incidence of autism in the child (Kong et al., 2012). This is because sperm cells arise from dividing precursor cells, and they acquire new mutations each time they divide as a result of errors occurring during cell division. Thus, the older the father, the more errors and possible mutations that may have occurred in his sperm and therefore the greater the risk of the child having new mutations in his or her genome related to autism that were not present in either parent's genome, a relationship that was borne out through whole-genome analyses of fathers in Iceland. The increase in risk is not massive, and autism still does not have a high probability of occurring in children of older fathers, but it may help explain the increase in the incidence of autism in many developed countries, where the age of fathers has also been increasing.

Q: What is the evidence for a genetic basis for autism and related disorders?

There was an early environmental theory of autism, commonly called the "refrigerator mother" scenario (Bettelheim, 1972), a socialization theory that has since been discredited. Clinicians had thought that autistic children were disproportionately from middle- and upper-class families, and they hypothesized that the mothers in those families were often cold and disengaged from their children, creating such a violation of the normal attachment sequence as to cause autism. One problem with the greater incidence of cases of autism in children of better-educated parents, however, may be that those parents are more likely to refer the children to specialists who diagnose autism, creating a **sampling bias**. Consequently, the refrigerator mother theory has not held up over time. There is no evidence that a colder, more dispassionate parent causes a child to develop autism. Nonetheless, there may be a modest correlation between socially nonresponsive parents and autistic children because they share a genetic tendency to be emotionally limited in social interactions.

Q: Describe a socialization theory of the origins of autism, and comment on its limitations.

Other environmental factors have been found to be associated with autism, although the direction of causality is often unclear. Researchers have found that various infections in early infancy or prenatally are associated with higher levels of autism (Atladottir et al., 2010, 2012). For example, children with autism are likely to have higher levels of antibodies associated with having had various viral and bacterial infections (Hornig & Lipkin, 2001; Patterson, 2011). This pattern is often interpreted as indicating that children with autism (or their mothers) have had a higher incidence of various infections early in development, although it is also possible that they may have more active immune responses to infections or that autism early on could lead to greater susceptibility to infections. Other work suggests that autistic individuals may have more immune-related diseases, such as autoimmune disorders (Patterson, 2011; Trottier et al., 1999). Indeed, one view suggests that as many as one-third of the cases of autism may result from problems of immune system regulation in the mother, sometimes as a side effect of an infection, but other times simply because a poorly regulated immune system results in inflammatory disease that influences fetal brain development (Velasquez-Manoff, 2012).

More broadly, a wide array of environmental factors, ranging from infectious diseases to exposure to insecticides, has been seen as potentially related to the onset of autism. In addition, when such effects do occur, they may be produced through gene-environment interactions. For example, a particular kind of environmental exposure might influence a genetic mechanism regulating a specific aspect of neuronal development (Pessah & Lein, 2008). Environmental factors on their own may not be sufficient to trigger the onset of autism in most individuals, but these factors may have such effects in a special subset of individuals who are at risk because they have a certain genotype. Such gene-environment interaction patterns are often described in terms of the **diathesis-stress hypothesis**, which proposes that some individuals have a genetic or biological vulnerability (a "diathesis") that causes them to be more likely to show a disease when immersed in a stressful, negative environment. At the present time, however, the research community has not achieved much consensus on the links between specific environmental factors and autism spectrum disorders.

Anxiety Disorders

We all have observed children who are more fearful and anxious than others. Within the normal spectrum, we can simply attribute variations of anxiety and fearfulness to different personality types. Similarly, the different attachment styles that we considered in Chapter 6 do not in themselves indicate psychopathology. But in some cases, anxieties can become so strong and persistent as to be debilitating for the child, interfering with the child's normal functioning and thereby becoming a form of mental illness known as an **anxiety disorder**. Anxiety disorders can cover a wide spectrum of problems, ranging from severely insecure attachment styles to phobias to obsessive-compulsive disorders. In this section, we will focus on generalized anxiety disorder, separation anxiety disorder, and social anxiety disorder, having briefly discussed phobias in Chapter 7 in the context of prepared fears. We will then discuss obsessive-compulsive disorder as an anxiety-related disorder that has some distinctive components that do not affect all people with anxiety problems.

Incidence of Anxiety Disorders

Considered collectively, anxiety disorders are the most prevalent mental illness in children, with incidences approaching 15 percent of children between ages 9 and 17 (Cartwright-Hatton et al., 2006; Costello et al., 2005; Muroff & Ross, 2011; Southam-Gerow & Chorpita, 2007; Velting et al., 2002). Anxiety disorders seem to be about equally common among boys and girls in childhood, but they become more common among girls in adolescence (Kashani & Orvaschel, 1990; Kubarych et al., 2008; Nielsen et al., 2000). Anxiety disorders are among the earliest psychopathologies to emerge, with patterns of anxious behavior in infancy predicting social anxiety many years later—probably even in adulthood. Moreover, when anxiety problems are identified in children, they are highly likely to be predictive of long-term problems. For example, the child who is excessively anxious about school tests, parties, and athletic events is more likely to have severe anxiety problems as an adult, and often depression as well (Bernstein et al., 1996; Brady & Kendall, 1992; Southam-Gerow & Chorpita, 2007).

Q: Describe the prevalence of anxiety disorders in children.

Anxiety and fearfulness can first manifest themselves in the young infant. We saw in Chapters 6 and 7 that preverbal infants can vary considerably in the degree to which they become alarmed or upset by novel or mildly threatening stimuli. Moreover, some infants seem much more inhibited than others around novel stimuli, exhibiting fearfulness and withdrawal, as seen in Chapter 7. Infants who are highly inhibited in infancy are more likely to show social anxiety disorder and generalized anxiety disorder as adolescents (Chronis-Tuscano et al., 2009; Khalid-Khan et al., 2007; Schwartz et al., 1999, 2003; Trentacosta et al., 2008; White et al., 2011). **Social anxiety disorder** tends to involve fears and anxiety about social situations or situations in which a person is being evaluated by another (see Figure 16.3). This disorder can lead to either avoidance of such situations or to high levels of discomfort when the person is in those situations (Muroff & Ross, 2011). **Generalized anxiety disorder** involves excessive levels of worry about a wide range of

FIGURE 16.3 **Social anxiety disorder.** Most people feel some anxiety in front of groups, but when the anxiety becomes so strong that the individual cannot even look at others, it may be a sign of social anxiety disorder. Social anxiety disorder often becomes most salient when children are in middle school.

situations. A child with such a disorder might worry excessively about an upcoming trip to the zoo, whether she will have to use the toilet at school, and whether her school bus will crash on a field trip. If the worries are more focused on just social situations, the disorder is a social anxiety disorder. If the worries are primarily about a particular fear, such as a fear of large dogs, the disorder is a phobia.

Developmentally, the earliest signs of anxiety are seen in the form of separation anxieties (discussed as separation distress in Chapter 6), with some children showing excessively fearful and anxious responses upon separation from a parent or other adult caregiver. Specific phobias are usually the next disorder to appear, often before 7 years of age. Generalized anxiety disorder doesn't usually appear until around age 9 or 10 (Muroff & Ross; 2011; Southam-Gerow & Chorpita, 2007). Social anxieties tend to become more prominent around age 12, while panic disorder (a disorder in which panic attacks occur frequently and for no obvious reason) doesn't usually occur until around age 15 (Southam-Gerow & Chorpita, 2007). With the exception of children with panic disorder, children who show one kind of anxiety disorder are more likely to show other kinds of anxiety disorders as well, suggesting some shared underlying causes (Muroff & Ross; 2011; Wood et al., 2003).

Taking a closer look at the anxiety disorders, we observe that anxiety manifests itself differently throughout development. Most notably, for both normal and abnormal cases of anxiety, the objects that produce anxiety tend to change with age. Younger children tend to worry more about physical objects or threats to their person (will they fall off a bridge, will a trip to the dentist be painful), whereas older children might worry about behavioral performance (will they do well on a test, will they be able to remember their way home) or about social and psychological threats (will they be disliked by others, will they be too nervous to speak in front of the class) (Gullone, 2000; Westenberg et al., 2004; Wood et al., 2003).

Q: How do anxiety disorders tend to change with increasing age?

Causal Factors

There have been several theories about how and why anxiety disorders emerge in children, ranging from those that focus on the biological components, like the genetic basis for cortical circuits that inhibit behaviors (see Chapter 7), to accounts that refer to a child's early experiences, such as patterns of parenting (see Chapter 6). Freud described cases of anxiety arising out of internal conflicts. In one of his most colorful accounts, he described the case of "Little Hans," who supposedly acquired a phobia of horses because of an Oedipal conflict in which he saw the horse as proxy for a castrating father (Freud, 1909). By contrast, we saw in Chapter 4 how John Watson instilled anxiety in a child through classical conditioning, a technique that tried to deny any value to considering mental states in the child (Watson & Rayner, 1920). Here, however, we focus mostly on generalized anxiety disorder, in which a child seems to be anxious about a wide range of events and possible futures and not about a highly specific object, as in the case of phobias.

Insecurely attached infants and children are more likely to show anxiety problems later on (Brumariu & Kerns, 2011; Cassidy & Berlin, 1994; Colonnesi et al., 2011; Esbjørn et al., 2012; Thompson, 2001). As is often the case with attachment-related research, however, it is difficult to assess causal directions. While it might be that parents who are insensitive to children's needs may cause children to become more anxious, it is also possible that anxious children cause parents to behave in ways that make the parents appear to be insensitive. Moreover, there are associations between depression in mothers and increased anxiety in children (Feng et al., 2008; Pilowsky et al., 2006). Such associations may reflect the influences of unresponsive mothers or the modeling of anxiety by depressed mothers (Gerull & Rapee, 2002). In fact, researchers have shown in experimental studies that when parents are told to model anxiety-reducing behaviors, children show less anxiety toward potentially anxiety-inducing stimuli (Egliston & Rapee, 2007). In addition, when mothers go into remission from depression after treatment, their children show improved mental health, with one measure involving reduced levels of anxiety (Wickramaratne et al., 2011). Thus, beyond any shared genotype effects, parental behavior seems to also influence a child's level of anxiety, at least in specific contexts.

Cognitive Factors Children with anxiety disorders tend to be apprehensive about the present and to worry a great deal about the future. They tend to engage in **catastrophizing**, assuming the worst possible outcome for future events, even when those outcomes are highly unlikely or implausible. These features are considered central to diagnoses of anxiety disorders (American Psychiatric Association, 1994). Researchers looking for ways in which children with anxiety disorders might be cognitively different from children who do not have anxiety disorders have therefore asked whether anxious children show a higher preponderance of some kinds of cognition as opposed to children who are not anxious.

A range of studies suggests that there are more negative cognitions in anxious children. For example, when researchers asked children to describe the cognitions they had had during a previously taken test, anxious children tended to report higher numbers of negative cognitions (thoughts like "I did not do well on the test" or "I incorrectly answered most of the questions") than children who were not anxious (Hogendoorn et al., 2012; McDonald, 2001; Prins & Hanewald, 1997). The same pattern emerged when researchers presented children with ambiguous stories about social situations and asked the children to say when they thought the story started to be "scary" and how they themselves would feel if they were the protagonist in the story (Muris et al., 2002a). Socially anxious children ages 8 to 13 tended to hear fewer sentences of the stories before they decided they were scary—that is, they formed a judgment of the story as socially threatening earlier than children who were not socially anxious. In addition, the socially anxious children showed a higher overall incidence of labeling stories as threatening and displayed higher levels of negative feelings and cognitions as a result of listening to the stories than did children who were not anxious. It therefore appears that socially anxious children form different cognitive interpretations of social situations, even when they are bystanders, and that these interpretations result in higher perceptions of threats and higher levels of negative emotions (Gregory et al., 2007; Muris & Field, 2008). In addition, socially anxious children tend to perceive their own bodily indications of anxiety in more dramatic and public terms. For example, in socially stressful situations, they perceive their heart rate as faster and more noticeable to others than do children with low social anxiety who have the same actual heart rate (Schmitz et al., 2012).

Q: How might a child's cognitions be involved in precipitating or maintaining generalized anxiety or social anxiety?

Anxious children appear to have cognitive biases that contribute to anxiety in several different ways. They have attentional biases that lead them to pay more attention to aversive and distressing stimuli, and they have greater difficulty disengaging from such stimuli. They have interpretation biases that lead them to make more negative interpretations of ambiguous situations that other children might see as neutral or even positive. Finally, they have memory biases that lead them to recall more negatively charged aspects of prior events. These different biases can be integrated into a single model, as shown in Figure 16.4 (Muris & Field, 2008).

Children who are socially anxious may have less developed social intelligence, making it more difficult for them to understand the nuances of delicate social situations (Sood & Kendall, 2007; Southam-Gerow & Kendall, 2000). Their anxiety may arise from difficulty in understanding their own emotional states as well as those of others. Or it may result from particular difficulties in understanding the relation between cognition and action and between different emotional and cognitive states that may co-occur in the same mind at the same time. These difficulties may create a default bias to assume that when in doubt, the social

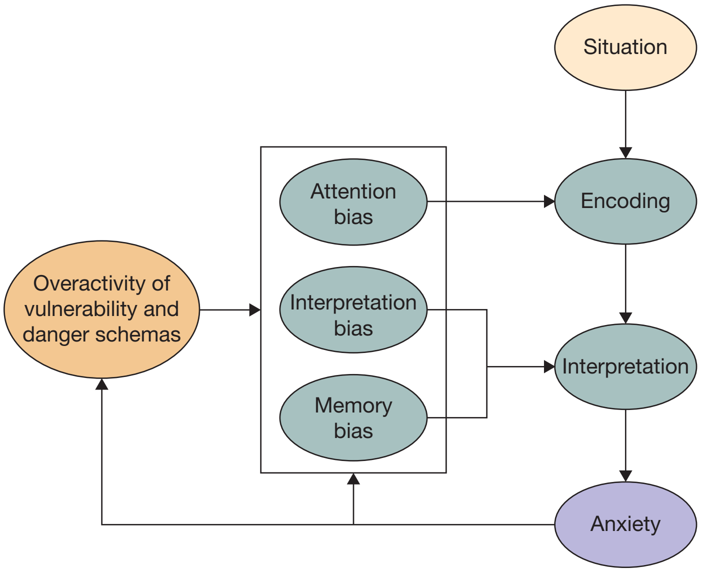

FIGURE 16.4 Cognitive and attentional biases contributing to anxiety disorders in children. Children with anxiety disorders show (1) more attention to and more difficulty disengaging from disturbing stimuli, (2) a tendency to interpret ambiguous events in more negative ways, and (3) selective recall of memories of events that are more negatively charged. Adapted from Muris & Field (2008).

situation is a threatening one. A better understanding of all children's abilities to grapple with multiple simultaneous emotions and cognitions may therefore be essential to understanding how social anxiety disorder develops and changes as the child develops (Choe et al., 2005).

We discussed phobias briefly in Chapter 7. The main point here is that individual differences in the tendencies to form phobias may be related to generalized anxiety disorder in children. Thus, the child who always imagines worst-case scenarios and who cannot disengage from thinking about all that could go wrong in a present or future situation may well be more likely to develop and maintain phobias than less anxious children. All children can develop phobias, and the phobias are constrained by preparedness phenomena of the sort discussed in Chapter 7, but anxiety may help exacerbate the process.

Biological Factors Across many twin and adoption studies, researchers have consistently found evidence for genetic influences on anxiety (Gregory & Eley, 2007; Rapee et al., 2009; Sakolsky et al., 2012). Most studies have focused on genes associated with the production and regulation of the neurotransmitter serotonin, but other studies have suggested links to genes associated with other neurotransmitters, such as dopamine, and genes associated with stress-related hormones. In addition, the association between genes and anxiety disorders can be stronger in some environments than in others (Fox et al., 2005; Sakolsky et al., 2012). For example, variations in genes that regulate serotonin show significant relations to anxiety when children are in families that have low levels of social support. In families with high levels of support, however, the same patterns of variation are not related to anxiety. This is a gene-environment way of understanding the notion of being "at risk"—namely, some children may be genetically predisposed to show a disorder but only in a certain range of environments.

In general, genetic factors don't just act on their own; rather, they interact with both environmental and cognitive factors. Thus, genetic influences on attention and memory might in turn influence some forms of anxiety. Similarly, some kinds of family environments might make a child more susceptible to genetic influences. Finally, environments might even trigger the turning off or on of a genetic regulatory pathway.

Obsessive-Compulsive Disorder

As seen at the beginning of this chapter, some children can develop a series of behaviors that involve a high level of anxiety as well as high incidences of checking various things, persistent, intrusive thoughts that cannot be ignored or set aside, and highly repetitive behaviors (American Psychiatric Association, 2000; Leckman et al., 1997). This pattern of behaviors is known as **obsessive-compulsive disorder (OCD)**.

Types of Obsessive-Compulsive Disorder Let's consider in more detail the four main types of obsessive-compulsive disorder that researchers have repeatedly proposed (Bloch et al., 2008; see Figure 16.5). One cluster of behaviors revolves

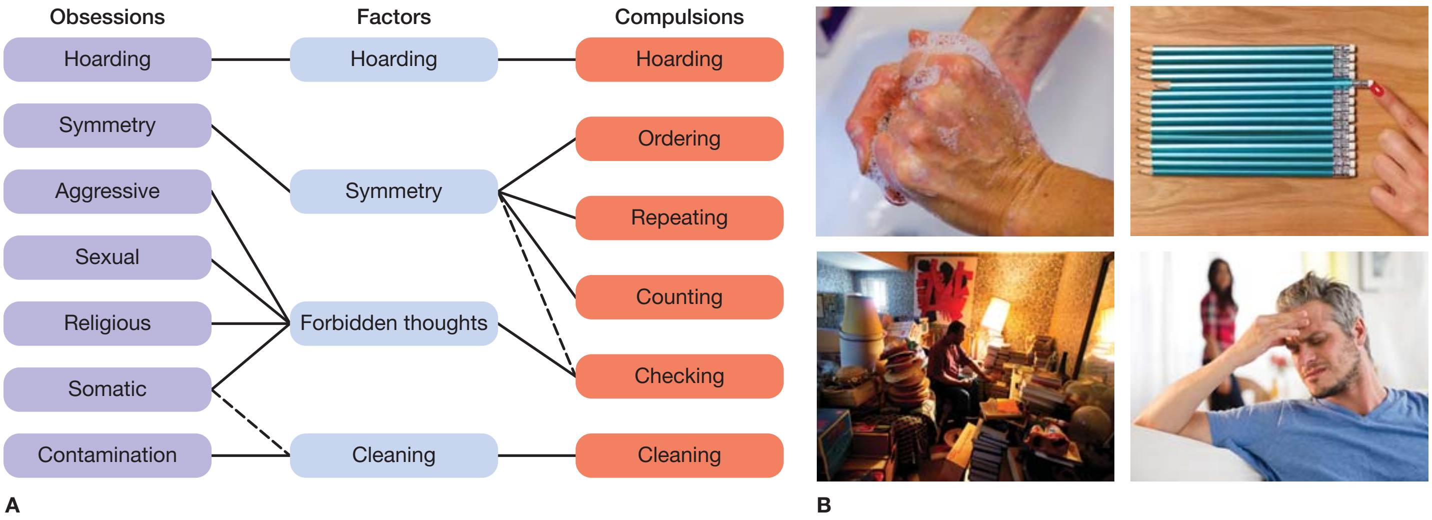

FIGURE 16.5 Clusters of symptoms in obsessive-compulsive behaviors. Obsessive-compulsive behaviors are often classified into four types or factors, with characteristic obsessions and compulsions, which can overlap somewhat: cleaning and contamination fears, a desire to order things, hoarding of objects, and forbidden thoughts (usually aggressive, blasphemous, or sexual).The diagram shows solid lines for links between obsessions or compulsions and factors that can be found in both adults and children, and dashed lines for links between obsessions or compulsions and factors found only in children. Adapted from Bloch et al. (2008).

around fears of contamination and is accompanied by compulsive cleaning. A person might obsess about dirt, germs, or other forms of contamination and might engage in compulsive cleaning and washing to reduce anxiety about the contamination.

A second cluster revolves around an obsession with order and symmetry and is accompanied by compulsive ordering, repeating, and counting behaviors. A person with this cluster might repeatedly line up a set of objects in a precise and symmetrical manner, or a child might take all of his toys and carefully arrange them in a neat geometric pattern.

A third cluster revolves around an obsession with losing things that may be of importance and is accompanied by hoarding behavior in which a person is extremely reluctant to throw anything away for fear it might be needed someday. People can hoard everything from used pieces of aluminum foil to old magazines to bottle caps.

Finally, a cluster revolves around unwanted aggressive, sexual, or religious/blasphemous thoughts or excessive somatic (bodily) worries about catching severe illnesses, such as cancer or AIDS. A person with this cluster might be plagued with highly unwelcome thoughts about assaulting another person or engaging in a horrible transgression of his or her religion. Attempts to reduce the anxiety associated with such thoughts might often take the form of compulsive checking behavior, such as going back to make sure the apartment is locked a dozen times or looking both ways 20 times before crossing a street.

These four clusters are found repeatedly when we look across cultures (Matsunaga et al., 2008; Pallanti, 2008; Torresan et al., 2009). In addition, there are reports that each cluster involves somewhat different brain structures (Maia et al., 2008). Across all types, however, there is a common theme of a debilitating obsession that creates anxiety and of compulsive behaviors that are attempts to reduce that anxiety. In addition, some individuals can show symptoms from more than one cluster (Calamari et al., 2012).

Incidence of Obsessive-Compulsive Disorder Obsessive-compulsive disorder is estimated to occur in about 2 to 3 percent of the general population (Calamari et al., 2012; Gilbert & Maalouf, 2008; Jenike, 2004; Karno et al., 1988). The incidence may be even higher because many people afflicted with the disorder go to great lengths to conceal it from others because they sense how irrational it is. By contrast, younger children are less self-conscious and less likely to feel the need to conceal their behaviors. The incidence is reported to be roughly 1 to 2 percent in children and adolescents.

Although obsessive-compulsive disorder has been reported in 2-year-olds (Rapoport et al., 1992), it is normally first noticed in children between 6 and 15 years of age (Gilbert & Maalouf, 2008). When the disorder appears in young children, it is more likely to be seen in boys, but by adolescence the distribution between the sexes becomes more even. There is a second, later period, between ages 20 and 29, in which another wave of onsets of the disorder is seen. This later period, combined with the shifting gender ratios, leads some to suggest that early-emerging obsessive-compulsive disorder may have a somewhat different basis than the disorder that first emerges in young adults (Taylor, 2011).

Diagnosis of Obsessive-Compulsive Disorder The diagnosis of obsessive-compulsive disorder relies on several converging forms of evidence. Although there are no simple genetic markers or other physiological markers of the disorder, there are some physical signs that can indicate some variants of the disorder. Thus, simple examination of the red hands of a compulsive hand washer or the bleeding gums of a compulsive tooth brusher can help confirm a diagnosis. Behaviorally speaking, we can ask if engaging in the behavior seems to reduce anxiety but is not enjoyable in its own right (for example, washing hands may reduce anxiety but may not be at all pleasurable). These behaviors can be quite time-consuming, often taking well over an hour each day. More cognitively, the obsessions, in addition to falling into categories such as contamination, loss of objects, and ordering, also tend to consist of unrealistic concerns. The obsessions are usually unwelcome and intrusive thoughts that adults, at least, will often regard as not making any sense and will frequently regard with fear and disgust. Diagnosis in children is the same as in adults except that, unlike adults, who normally are aware of the irrationality of their compulsions and/or fears but cannot stop doing them, the children may not have such an explicit awareness (American Psychiatric Association, 2000).

It is interesting that the diagnostic criteria for obsessive-compulsive disorder in children do not require any awareness that the compulsion is irrational. Moreover, younger children with the disorder often do not consciously think about or discuss the threats that they are trying to avoid. Thus, while adults might say that they are afraid of getting germs when they are asked why they excessively wash, younger children might simply say that things do not feel right. It seems as if, in its early stages, obsessive-compulsive disorder involves self-protective behavior programs that get triggered by stimuli so minor that they are not even noticed and then are set in motion with little or no thought as to why. Even in adults, it is not uncommon for a patient to develop a compulsion before having a good reason for it, with the reason emerging later, often as a form of "discovery." For example, one patient who had a set of compulsions around contagion and contamination for many years learned about AIDS and declared that the compulsive behaviors had always been to avoid getting AIDS, even though the behaviors began before AIDS was publicly known (Rapoport, 1989).

Causal Factors Compulsions may originate in the normal levels of ritual and repetitive behavior in young children (Leckman & Bloch, 2008; Leonard et al., 1990; Thomsen, 1998). Children younger than 3 years old often engage in such behaviors, which then gradually die out in toddlerhood. It may be that obsessive-compulsive disorders lead to the retention and elaboration of such behaviors rather than the normal course of decay.

Q: What are some examples of obsessive-compulsive behaviors in young children?

Many behaviors associated with OCD, including cleaning and checking, may be part of a **security motivational system** that is part of many animals and is built to recognize and respond to very subtle and indirect cues to danger, including cues to predators, toxins, and other possibly harmful changes in normal routines (Szechtman & Woody, 2004). Such a system is thought to be a separate module that is akin to modules for language and spatial cognition and that may have four distinctive features: (1) risk detection of potential dangers, (2) easy activation and slow deactivation, (3) orientation toward action designed to reduce the likelihood of future dangers (such as checking behavior), and (4) orientation toward prevention of future events as opposed to avoidance of present ones.

The security motivational system recognizes a "feeling of knowing" that appropriate protective actions have been taken, which serves as a signal for the system to shut down. In normal circumstances, a person appraises his actions, concludes that he has taken all reasonable precautions, and reduces his levels of threat prevention. According to this theory, cases of obsessive-compulsive disorder seem to involve blocking information that prevents a person from feeling that he has taken all reasonable protective actions. As a result, the person continues trying to protect himself because "things just don't feel right," even though at a more rational level he knows full well that his hands must be clean, the oven must be off, or the house must be locked. Here the problem of OCD is less a cognitive issue and more related to emotion—namely, getting the feeling of assurance or "satiation" in the activity that causes the person to feel that he has done enough and can stop his self-protective behaviors (Szechtman & Woody, 2004). The process is thought to be analogous to cases of physiological satiation. For example, if someone is thirsty, the awareness of having just drunk a lot of water can induce a feeling of satiation long before the water is absorbed into the body.

Q: How has the presence of a security motivational system been used to explain the emergence of obsessive-compulsive disorder?

In short, obsessive-compulsive disorder may arise from a relatively modular threat anticipation/avoidance system that, while involving a high level of anxiety, works quite differently from the system leading to other fears. Its modular nature allows compulsions to be set up and maintained largely outside of conscious control. Most models of the disorder in adults put a heavy emphasis on cognitive factors, assuming that obsessional thoughts help trigger and maintain the compulsions. But in young children, and by some accounts perhaps in adults as well (Szechtman & Woody, 2004; Woody & Szechtman, 2011), the obsessions may not precede the compulsions as much as follow them. Development may promote a growth of unwanted obsessive thoughts that enhance the already present compulsions and that ultimately can take on a life of their own, leading to new forms of compulsions (for example, counting words in sentences or the number of streetlights passed) that may depart more and more from those evolutionary ancient ones (for example, excessive washing to avoid contamination). At all ages, the compulsions tend to be more common in times of stress, suggesting again that a relatively automatic vigilance system gets put into action trying to discover subtle and often nonexistent cues to threats and ways to avoid them. Developmental differences in the manifestation of obsessive-compulsive disorder (such as a higher incidence of checking behaviors with increasing age) may be critical to understanding the different cognitive and emotional components of this disorder (D. Geller et al., 2001).

Problems identifying the source of their memories (see Chapter 10) may also contribute to the incidence of compulsive behavior in children, who may have more difficulty knowing whether they have really performed an action or just thought that they did and therefore perform it again. Because younger children in general have greater difficulty identifying the sources of their memories (for example, whether the memories come from a dream or from a real-life experience), a child concerned with contamination may have more difficulty accurately remembering whether he washed his hands or just thought about doing so.

Why do some children develop obsessive-compulsive disorder and others do not? There are several distinct models of etiology, many of which could mutually contribute to the disease. There are clear indications of a genetic basis, as the incidence of OCD in MZ twins is roughly twice that in DZ twins (approximately 80 percent versus 40 percent concordance rates), with far higher concordance rates for OCD than for most other anxiety disorders (Carey & Gottesman, 1981; Pauls, 2008, 2012; Pauls et al., 1995; Rasmussen, 1993). Alleles linked to higher levels of OCD are often involved in serotonin-related pathways (Abudy et al., 2012; Taylor, 2013). In addition to a genetic basis, adverse neurological events in infancy and early childhood may cause the disorder. These may include birth difficulties, responses to various infections such as meningitis, autoimmune reactions, or even brain damage from an accident (D. Geller et al., 2008; Jenike et al., 1998).

In contrast to the strong evidence for biological factors causing obsessive-compulsive disorder, there is far less evidence for psychological models, such as the Freudian idea that failures to progress normally through toilet training and the anal stage lead to disorders of control (Sears et al., 1957). There simply doesn't seem to be any good reason to believe that a particular type of parenting causes the emergence of obsessions and compulsions. In a sense, this may be a bit surprising. It might seem that a parent who constantly worries about potential future threats and models endless checking behaviors might well instill such behaviors in the child, and such associations between parental overprotectiveness and childhood OCD have been found (Wilcox et al., 2008). But when the genetic commonality is taken into account, it is difficult to find an independent contribution from patterns of child rearing. One final route for parental and broader environmental influences might simply be one where increased stresses cause a rise in obsessive-compulsive behavior in children who are already at risk for the disorder. Thus, if a child with a tendency for obsessive-compulsive behavior is repeatedly put into circumstances that raise anxiety, that heightened anxiety may trigger obsessive thoughts and compulsive behaviors.

Q: What are the most likely causes of obsessive-compulsive behavior in children?

Eating Disorders

One of the most striking developmental phenomena in psychopathology is the emergence of certain eating disorders in early adolescence, with a significant preponderance of the disorders appearing in girls. There is an immense literature on eating disorders that normally divides the disorders into anorexia nervosa, bulimia, and binge eating, while also allowing for other rarer forms of eating disorders, such as fixations on the "right" foods (Brownell & Foreyt, 1986; Keel et al., 2012). These disorders can have devastating health consequences. For example, girls with anorexia nervosa are 12 times as likely to die in a given year as girls who do not have the disorder (Smink et al., 2012; Sullivan, 1995).

The incidence among teenage girls of all forms of eating disorders is estimated to be as high as 3 percent (Favaro et al., 2003; Hoek, 1995; Hsu, 1996; Smink et al., 2012). The age of onset of anorexia nervosa and bulimia nervosa appears to be decreasing in younger generations, although still occurring in the teen years. This earlier onset is associated with earlier age of menstruation, a reduction in number of siblings, and higher levels of socioeconomic status, although the specific causal relations among these factors remain unclear (Favaro et al., 2009). The incidence among girls younger than 9 years old is vastly lower, usually reported at well under 1 percent for anorexia nervosa, bulimia, and binge eating (Nicholls & Bryant-Waugh, 2009; Smink et al., 2012). Anorexia nervosa occurs less than one-tenth as often among boys than girls in all age groups, and bulimia occurs in boys at about one-hundredth the rate among girls (Hoek & van Hoeken, 2003; Levine & Piran, 2005; Smink et al., 2012). It should be noted, however, that the prevalence may be underestimated because so many people afflicted with these disorders go to great lengths to conceal them.

Eating disorders in general have several common properties: they are more common in girls, often much more common; they usually first emerge in adolescence; and they are often associated with nonoptimal family structures. Their absence in younger children is probably not due to a limitation imposed by younger children's cognitions as much as it is a function of the sorts of physical and social changes that are associated with entering puberty and how the child, her family, and the culture at large relate to those changes. The two most commonly discussed eating disorders are anorexia nervosa and bulimia nervosa. A brief summary of the contrasting diagnostic criteria of these two eating disorders is given in Table 16.1. We will discuss each in turn.

Anorexia Nervosa

Anorexia nervosa is distinguished by a person's intentional refusal to eat anything beyond minimal amounts of food. It may be a way for an achievement-driven girl to demonstrate her own form of control in situations in which she

Anorexia Nervosa	Bulimia Nervosa
Body weight voluntarily maintained at below normal level	Large uncontrolled eating binges at least twice weekly
Intense fear of gaining weight or becoming fat	Inappropriate compensatory behavior (e.g., vomiting)
Amenorrhea (in females)	Self-esteem closely linked to body weight/shape

TABLE 16.1 Key diagnostic features of anorexia nervosa and bulimia nervosa. While both eating disorders are much more common in females than males, they have distinct characteristics. In addition to the diagnostic features described here, anorexia nervosa has a slightly earlier age of onset than bulimia nervosa and has been a more consistent disorder both historically and cross-culturally. It also has been more closely associated with genetic influences. From Walsh & Devlin (1998).

feels powerless. Adolescents with anorexia nervosa tend to have extremely low body weights, and their self-esteem is based on an excessive concern with being thin rather than on their intellectual skills, personality, or physical skills (see Figure 16.6). A preoccupation with a high level of exercise is also often observed. Anorexia is also associated with **amenorrhea**, the absence of a menstrual period in women who are of menstrual age. Anorexia in a child is frightening for parents because they feel powerless to stop their child from wasting away.

Incidence of Anorexia As indicated earlier, this disorder shows the strongest bias toward girls, occurring at least 10 times as frequently in girls as in boys. The disorder is very rarely seen before middle school, although a very small number of cases of what seems to be the disorder have been reported in girls under age 10 (Bostic et al., 1997; Rhodes et al., 2009; Watkins & Lask, 2002). It typically appears around age 12, reaches its height in adolescence and college, and then gradually wanes, although it may continue to be seen in middle age (Keski-Rahkonen et al., 2007; Smink et al., 2012). Anorexia often co-occurs with other forms of psychopathology, especially depression and anxiety-related disorders.

The disorder has been reported in various forms for centuries (Vandereycken & Van Deth, 1994). But given some of the popular press on the topic, it might seem as if there has been a surge of anorexia cases in recent years, perhaps even an epidemic. A closer look at historical patterns, however, suggests only a modest rise over the course of the twentieth century, with drops sometimes occurring in recent years (Currin et al., 2005; Keel & Klump, 2003; Keel et al., 2006; Smink et al., 2012). The contemporary media's emphasis on the desirability of very thin bodies may have helped contribute to that modest increase, but the more important pattern is that, for centuries, in the context of religious fasting or simply worrying about being thin, anorexia nervosa has occurred in a higher proportion of girls than boys, with the huge sex difference remaining relatively constant over that period (Brumberg, 1988).

It had long been held that anorexia nervosa was a disorder that was more common among those in the upper socioeconomic classes and among those in advantaged groups that had more achievement-driven girls trying to assert control. While there is some support for this view (Levine & Piran, 2005; Pate et al., 1992), analyses of reports of the disorder do not always show a preponderance of cases in the upper ranges of the socioeconomic spectrum (Forman & Goodman, 1999; Gard & Freeman, 1996). Rather, there are reports of higher incidences of anorexia in more technologically advanced societies that tend to have an abundance of food for their citizens (Miller & Pumariega, 2001). It may be that cultural factors are becoming more important than socioeconomic factors as all members of a culture, rich and poor, start to adopt standard images of the ideal body shape for that culture (Lake et al., 2000; see also Kayono et al., 2008; Keel & Klump, 2003).

We saw in Chapter 15 how the introduction of Western television programming into traditional communities in Fiji was related to an increase in eating disorders based on an "idealization of thinness" as depicted in the Western programs. Even this commonly reported cross-cultural finding, however, needs to be supported by large-scale

FIGURE 16.6 Anorexia in young adults. In 2010, the highly successful French model and actress Isabelle Caro died from complications related to anorexia. For many unfamiliar with the disease, it was baffling that such a successful and popular figure could actually die from the eating disorder.

rigorous comparisons of different cultures that use the same assessment instruments in the same way. For example, one problem is that some cultures may have much higher stigma attached to the disorder and therefore may have higher levels of underreporting by children to their families and by the families to their physicians. One extensive analysis of cross-cultural differences in anorexia found that while there may be some cultural variation in anorexia as a function of a culture's "idealization of thinness," anorexia is found in every culture in the world where the numbers and methods are adequate for reporting it (Keel & Klump, 2003).

Q: How does anorexia vary across gender and across cultures?

Cognitive Distortions in Anorexia A person with anorexia may report that she sees herself as fat and needs to be thinner, while others would say that she already appears to be extremely thin. Thus, there seems to be a form of distorted cognition in which a girl who by any objective account is incredibly thin still sees herself as fat or overweight. This distorted perception of one's body has been documented many times in the literature (Cash & Deagle, 1997; Exterkate et al., 2009; Keizer et al., 2012). The most common method to assess an individual's body image is to take a photo of the individual and then stretch the image on either a horizontal or vertical axis and ask the individual to adjust the image on those two dimensions until it fits with how she thinks she looks. Compared with participants who do not have eating disorders, an individual with anorexia or bulimia is more likely to adjust the image so that it portrays an individual as considerably heavier than she actually is. To make these simulated images more realistic, researchers have used software that allows participants to adjust several dimensions of their body image. In one study, participants were asked to adjust an image of themselves that showed their real weight and body shape, then to adjust the image to correspond to their ideal weight. As seen in Figure 16.7, participants with anorexia and bulimia were more likely to depict themselves as heavier than they really were. In addition, the participants with anorexia set up a considerably thinner ideal image (Tovee et al., 2003).

Many clinicians and researchers believe that such distorted images help set up and maintain anorexic behavior, and indeed many therapies are designed around the idea of shifting the distorted perception (Exterkate et al., 2009; Rosen, 1997). Nonetheless, the causal link between distorted body image and anorexic behavior remains largely speculative. For example, one issue is whether people with anorexia really "perceive" their bodies differently or whether they actually have the same perceptions as everyone else but respond differently because they want to convince others, and perhaps even themselves, that they are fat. One way to explore this issue is to develop more tasks that tap into very rapid perceptual processing of images that might not be as influenced by conscious response biases. For example, consider a set of photographs of an individual with anorexia in a natural setting, including head shots, full body shots, and partial body shots, where some of the shots were accurate and others were distorted to make the individual look heavier (as the person with anorexia normally seems to perceive her body). If those images were then embedded in a much larger set of images of other women of roughly the same age and the woman with anorexia was asked to identify herself as rapidly as possible when the images were presented in rapid succession, would the woman with anorexia actually be faster at identifying her "fat" self than her real self? This is just one example of the sorts of studies that researchers might conduct to assess how much anorexia is a problem in actual perception as opposed to response biases.

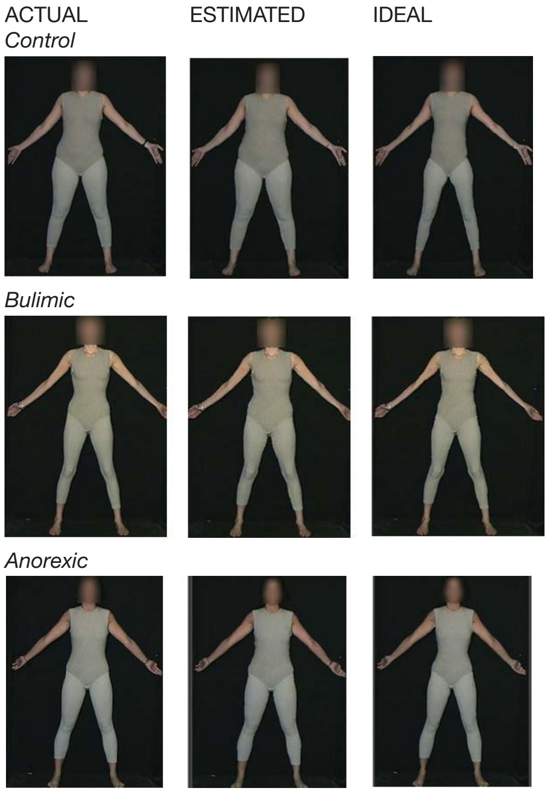

FIGURE 16.7 Body distortions by those with anorexia and bulimia. When computer software is used that simulates accurately how weight gets added to the body, individuals with both anorexia and bulimia will adjust the images in ways that show a distortion of their body image to higher weights than they really are. In addition, individuals with anorexia have an ideal body image that is thinner than the ideal shown by normal participants. From Tovee et al. (2003).

Q: How has the idea of distorted cognition or perception been supported by experimental work with girls who have anorexia?

Genetic and Environmental Causal Factors There is evidence of a genetic component for anorexia, with a higher concordance rate both for monozygotic twins and dizygotic twins (Bulik et al., 2000, 2007; Devlin et al., 2002; Klump et al., 2001; Thornton et al., 2011). Heritability estimates are at roughly 50 percent, which indicates a substantial genetic contribution. Specific genes also seem to be emerging as especially relevant to the disorder (Bulik et al., 2007; Grice et al., 2002). The causal pathways for genetic influences, however, remain unclear, although at least some scholars have wondered if there might be a link to certain cognitive styles related to obsessional thought, as described earlier.

Although 50 percent is an impressive degree of genetic influence, this still allows for substantial environmental influences as well. One theory of environmental influence, which also tries to explain the gender difference, focuses on the physical and physiological changes that happen in girls during puberty (see Chapter 1). As girls approach puberty, their bodies increase dramatically in certain dimensions, such as hip and breast size, and there is normally a considerable increase in the proportion of body fat. They also start to menstruate. Boys undergo quite different patterns of changes, often losing body fat and developing a body shape that is thinner than their prepubertal form. Given these differences, it has been repeatedly suggested that girls are more at risk for being upset with these body changes, especially in a culture that embraces thinness. Moreover, many girls may feel apprehension over the body changes associated with becoming a woman because of the increased sexuality that is implied and reinforced by the monthly recurrence of menstruation.

These speculations lead to an interesting prediction. In those who will develop anorexia, girls who mature earlier physically should show an earlier onset for the disorder than those who mature later. This prediction is borne out (Swarr & Richards, 1996). The effect of puberty itself, however, seems to be more modest when other factors, such as peer group and culture, are considered (McCabe & Ricciardelli, 2003; Tremblay & Lariviere, 2009). Moreover, the actual influence of body changes on anorexia may be caused more by the buildup of fatty tissue that occurs in puberty rather than by the actual onset of puberty itself. Thus, when the proportion of fatty tissue and the age of menstruation are looked at independently of each other, large increases in fatty tissue seem to be the primary predictor of body dissatisfaction (Lynch et al., 2008; Stice & Whitenton, 2002). To the extent that physical and physiological changes in girls' bodies are related to genetic factors, these genetic factors may also be indirectly related to the onset of anorexia. That is, if genetic factors cause a more rapid increase in fatty tissue in some girls, those changes may also put the girls at higher risk of developing anorexia.

Q: How have the gender differences in anorexia been explained? Which explanation seems to have the best support?

Family influences have often been thought to be an important factor in anorexia. Indeed, one family therapist, Salvador Minuchin, coined the term **anorexic families** to describe families in which particular patterns of interactions may be related to the emergence of anorexia in the child (Minuchin et al., 1978). Minuchin hypothesized that the parents in anorexic families have difficulty allowing their daughter to become more independent from the family in which she is enmeshed and to become an individual in her own right. In particular, anorexic families were said to have the following traits:

1. **Enmeshment.** A family structure in which everyone is so intertwined in their relationships and responsibilities that it is difficult for each member to emerge as an individual.
2. **Overprotectedness.** A family structure in which parents worry too much about a child's safety and tend to overreact to minor threats, resulting in not allowing the child to learn to cope in a more autonomous fashion.
3. **Rigidity.** A family structure in which there is an unwillingness to change the dynamics that constitute the dysfunctional family, including a tendency to stick to old patterns, no matter how painful they might be.
4. **Conflict avoidance.** A family that is unable to ever deal with conflicts or have useful confrontations. Parents avoid the conflict by withdrawing, refusing to respond, or otherwise escaping interactions over the conflict.

Collectively, these four factors were thought to drive some children toward seeking a way to exercise control and have autonomy. Supposedly, one of the few ways for them to do so is to exercise extreme control over their own bodies by refusing to eat, as this is the one pattern of behavior that the enmeshed, rigid, protective family environment cannot control.

Minuchin's hypotheses about the interactions of anorexic families were later tested in studies that compared the interaction patterns within families that had children with anorexia with the patterns of families that did not have children with anorexia (Casper & Troiani, 2001; Humphrey, 1989). In some studies, there are indications of different family dynamic patterns roughly similar to those proposed by Minuchin, but even in those cases, the causal argument does not follow directly, as parents may simply be manifesting a shared genotype with their children. Even Minuchin is careful to state that family factors might not initially cause anorexia, but rather they might maintain and perhaps exacerbate the disorder once it emerges. As is so often the case, the real causal pattern most likely involves a complex interaction of many social factors, with particular emphasis on genetic predispositions (Lacy & Price, 2004).

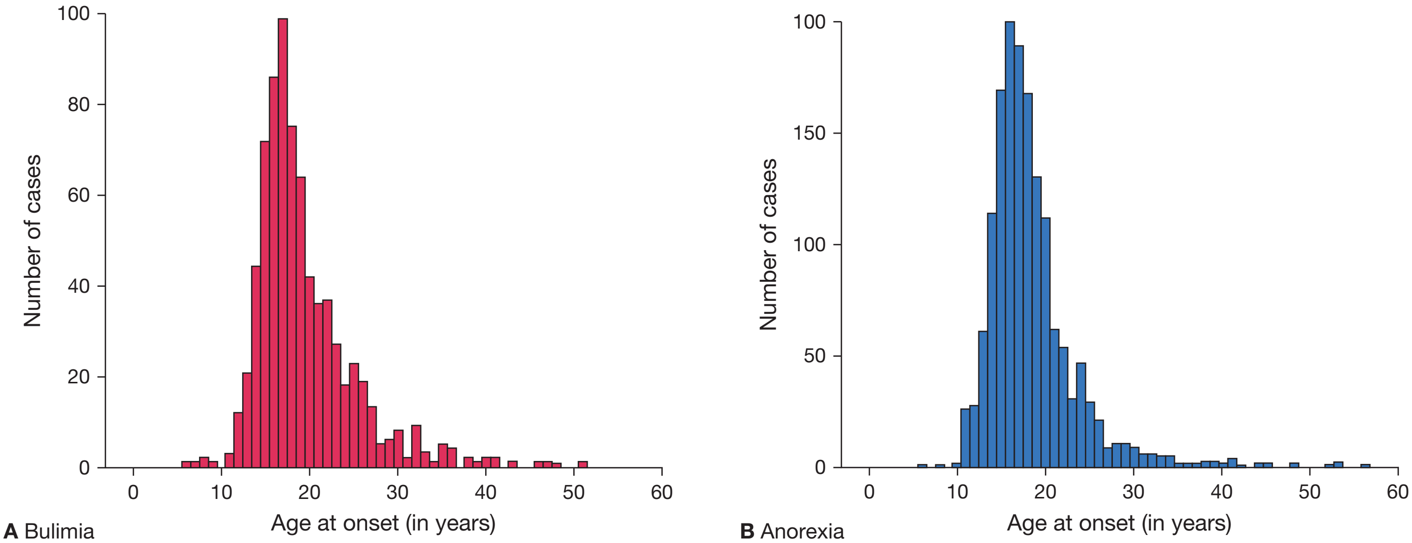
Q: Describe how family interaction patterns have been thought to be involved in the causation or maintenance of anorexia.

Bulimia Nervosa

Bulimia nervosa is an eating disorder that is quite different from anorexia. A person with bulimia will engage in huge bouts of excessive rapid eating two or more times a week and then follow those episodes of overeating with some way of purging the food, usually by self-induced vomiting. A person's anxiety and stress may trigger a bout of eating that is often accompanied by feelings of disgust toward her own body, with the purging then bringing a form of relief from the stress and negative feelings. In contrast to individuals with anorexia, those with bulimia tend to be of normal weight and can even be quite overweight.

Incidence of Bulimia As already noted, bulimia is much more common in girls than in boys (Carlat et al., 1997; Keski-Rahkonen et al., 2009; Smink et al., 2012). Bulimia is more common than anorexia, and it is observed at least twice as often (Favaro et al., 2003). Moreover, the disorder seems to have been documented more recently than anorexia, as it has been widely reported for only a few decades (Gotestam & Agras, 1995). This recent rise of bulimia fits with the observation that its prevalence also varies more dramatically across cultures than anorexia does, being essentially absent in some cultures while relatively common in others, such as in North America (Keel & Klump, 2003). As with anorexia, bulimia is virtually nonexistent in young children and then shows a significant rise in adolescence (see Figure 16.8).

Causal Factors While there is some evidence for a genetic component to bulimia, the strength of the evidence and the possible genetic conclusion is not as strong as it is for anorexia (Kaye et al., 2004; Keel & Klump, 2003; Waller & Sheffield, 2008). Bulimia may therefore be more strongly influenced by cultural and familial factors. In particular, cultures that put tremendous emphasis on thinness and stigmatize obesity may have higher levels of bulimia. One interesting indication of the power of cultural effects is found in a study of 9- and 11-year-old girls who were either in schools with considerably older children or in schools with children around their own age (Wardle & Watters, 2004). Being exposed to older girls in school was associated with the participants feeling more obese and being more concerned with dieting. Because the girls were essentially randomly assigned to the schools and the body weights did not differ between girls assigned to the different schools,



A Bulimia

B Anorexia

FIGURE 16.8 Age of onset of bulimia and anorexia. Despite being quite distinct diseases with different etiologies, the typical age of onset for bulimia is very similar to that for anorexia. Adapted from Favaro et al. (2009).

this study shows how a relatively small difference in school environment can create some of the psychological differences thought to be associated with eating disorders, especially bulimia.

Family influences have also been explored extensively. Mothers of girls who are bulimic tend to have a variety of traits that are different from the traits of other mothers. In one study, mothers of girls with bulimia were more unhappy about how their families functioned, more likely to have eating disorders themselves, had atypical patterns of dieting, and were more likely than other mothers to think that their daughters should lose weight. They were also more likely than other mothers to judge their daughters as less attractive than the girls judged themselves (Pike & Rodin, 1991). Parents of children with bulimia are also more likely to be depressed and to show less affection and more hostility and belittling in interactions with their children (Humphrey, 1989). Moreover, there seems to be a linkage between parental concerns about their children becoming obese and the children's eating behaviors long before the typical onset of bulimia in adolescence. In one study of infants and toddlers of mothers who had eating disorders (mostly bulimia), the mothers were more concerned about the baby's eating habits and the babies themselves were described as being more avid eaters, as if a fixation with eating had been set up very early in their lives (Agras et al., 1999). Again, however, claims of family influences need to be evaluated in the context of the alternative of a common genetic contribution to problems in both parents and children. The weaker evidence for genetic factors does at least initially lend more support for family and cultural influences in the case of bulimia.

Q: How do the most likely causes of bulimia seem to differ from the most likely causes of anorexia?

Depression

Everyone feels sad or blue from time to time, but some people fall into more sustained states of sadness and despair that become pathological. In adults, depression is a kind of affective (mood) disorder that has two prominent subtypes: unipolar depression and bipolar disorder. Each has its own course of progression. In children, the incidence of both types was long considered to be rare until at least some time in adolescence, raising profound questions about what factors protect most children from these potentially debilitating disorders.

A large set of adult studies suggests that these two types of depression are quite distinct clusters that occur in different groups of people (Angst & Marneros, 2001; Forty et al., 2008; Winokur et al., 1995; see Table 16.2). **Unipolar depression** is a severe and sustained drop in affect that is often accompanied by agitation, feelings of sadness and worthlessness, insomnia, and loss of appetite. It tends to be roughly twice as common in women as in men (6 percent of women versus 3 percent of men), a ratio that is present from early adolescence (Nolen-Hoeksema & Girgus, 1994). The most typical age of onset is in the 20s (American Psychiatric Association, 1994).

Bipolar disorder is a distinct affective disorder characterized by swings between periods of lethargy and low affect and periods of high activity, or "mania," in which the person often

Symptoms	Unipolar	Bipolar	Statistical Significance of Difference
Incidence of psychoses during depression	Half as common as in bipolar	Twice as common as in unipolar	Large
Number of lifetime episodes of depression	Somewhat less frequent	Somewhat more frequent	Moderate
Longest episodes of depression	Much longer	Much shorter	Large
Excessive self-reproach	More extensive	Less extensive	Large
Difficulty sleeping	Less difficulty	More difficulty	Large
Loss of energy	Greater loss	Less significant loss	Large
Diminished libido	More diminished	Less diminished	Large

TABLE 16.2 Bipolar disorder versus unipolar depression. Even in their depressive periods, people afflicted with unipolar depression have different symptoms and time courses than those with bipolar disorder. People with bipolar disorder have more frequent incidences of psychoses, more frequent episodes of depression, and shorter episodes of depression, among other differences. From Forty et al. (2008).

has inflated self-esteem, grandiose plans, increased talkativeness, and a diminished amount of sleep (American Psychiatric Association, 2013). It affects men and women equally (roughly 1 percent of the total population) and has an earlier average age of onset than unipolar depression, typically during late adolescence. People with bipolar disorder may have difficulty sleeping, but they are also more likely to have difficulty waking up in the morning. The genetic basis for bipolar disorder is considerably stronger than for unipolar depression. Loss of appetite is less common and may oscillate with binge eating. In the depressive phase, people with bipolar disorder are likely to be very slow in motor movements and not agitated as in the unipolar case. People with unipolar depression are more likely to display anger than those with bipolar disorder. Because of these differences, it is useful to think about the development of the two forms of depression separately.

Q: What are some differences in how depression is manifested in people with bipolar versus unipolar versions of the disorder?

Unipolar Depression

It was traditionally held that young children simply didn't get depressed. More recently, there seems to be a consensus that young children can develop true depressions that are similar to both the unipolar and bipolar types in adults (Coyle et al., 2003). This opinion is based on the ability to reliably use assessment questionnaires for childhood depression and because of convergences between what parents say about the behaviors of their children and the children's own self-reports (McClellan & Werry, 2000). The childhood assessments focus on factors that tend to be more behavioral in nature, such as problems in school and in social interactions and the presence of behaviors that are disruptive and aggressive. There are also indications of unpleasant or uncomfortable moods and an undervaluing of the self relative to others (Carle et al., 2008). Some children do seem to enter sustained periods of reduced affect and have some of the other symptoms found in adults, such as feelings of hopelessness about the future, excessive rumination about negative events, and suicidal thoughts. It is far less clear, however, that these children experience the full range of adult or adolescent symptoms. In fact, the recent flurry of attention to the presence of depression in young children runs the risk of overlooking much more dramatic developmental facts: the incidence of unipolar depression skyrockets during adolescence and swings from an even distribution among the sexes to a huge preponderance among females (see Figure 16.9). Unipolar depression, with its somewhat muted forms of negative affect with reduced intensity, increases markedly after 15 years of age (Hankin et al., 1998; see also Ge et al., 1994; Lakdawalla et al., 2007; Petersen et al., 1993).

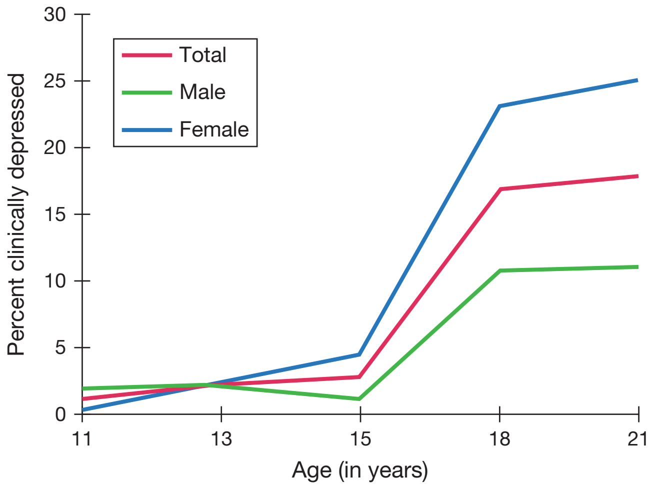


FIGURE 16.9 Rise of depression in adolescence. The incidence of clinical depression rises dramatically during the teenage years, especially among females. Adapted from Hankin et al. (1998).

Why is there such a dramatic increase in the rate of depression after puberty? Several possible reasons have been proposed: more stressful life events during and after puberty (Ge et al., 2001), increased interpersonal vulnerability (Gotlib & Hammen, 1992), physiological changes produced by puberty, and changes in cognition (Lakdawalla et al., 2007; Lockhart et al., 2002; Rutter, 1987). These accounts also attempt to explain why the surge in incidence coincides with the quite sudden onset of a large gender difference. Each of these factors is considered in exploring the etiology of childhood and adolescent depression.

Biological Causes Unipolar depression and its weaker variants tend to run in families, suggesting a genetic component. Indeed, in one study of severe depression among monozygotic and dizygotic adolescent twins, the much higher concordance rate among MZ twins suggested a heritability of roughly 40 percent (Glowinski et al., 2003; Lau & Eley, 2010; Rice & Thapar, 2009). Thus, even in cases of relatively early onset of the disorder, the heritabilities are as high as in adults, suggesting that the biological basis in adolescence may be similar to that found in older individuals. Moreover, if one individual in a family experiences depression in adolescence, the likelihood that a relative will also experience depression in adolescence increases based on how closely related the two individuals are (for example, MZ twins, DZ twins, non-twin siblings, or cousins), suggesting that genetics plays an important role in the onset of the disorder.

Genetic factors may often work in combination with daily life stressors, such that adolescents who have a particular genetic vulnerability may be much more likely to be plunged into depression when encountering a series of stressful life experiences, even though they may not fall into depression in less stressful environments (Hyde et al., 2008; Wichers et al., 2009). These extensive interactions with environmental influences may help explain why, despite high heritabilities, it continues to be difficult to isolate specific genes that are consistently associated with unipolar depression (Cohen-Woods et al., 2012). Such interactions also provide a good example of the diathesis-stress model of the development of psychopathologies, in which some individuals are seen as vulnerable to a specific psychopathology when exposed to stress.

Q: How does the incidence of depression change with development?

Genes can code for a wide variety of developmental changes, ranging from hormonal to cognitive changes, which has led researchers to investigate possible connections between hormone levels and depression. In particular, some studies have focused on whether the rapid changes in the levels of hormones circulating through the body during puberty, which differ between the sexes, could be related to girls' much higher rates of depression in adolescence. Despite the intuitive appeal of this hypothesis, however, the idea of a direct connection between adolescent hormone levels and depression has not been borne out by the research (Brooks-Gunn & Warren, 1989; Brooks-Gunn et al., 1994; Buchanan et al., 1992). In short, despite the popular idea that teenagers are being overwhelmed by "raging hormones," circulating levels of hormones in their blood have not been shown to directly affect their emotional states.

Nonetheless, there are good reasons to believe that there are indirect relations between hormones and emotions as a result of other processes. One possible influence may be that girls tend to mature earlier than boys and that those who mature especially early are put under social stresses at an earlier age owing to their changing bodies and appearance (Ge et al., 1996; Hyde et al., 2008). The 13-year-old girl who looks like a fully grown woman may encounter more social stresses than the 13-year-old who continues to look like a young girl for a few more years (Graber et al., 1997). By contrast, for boys, maturing early, when it does happen, may actually be a positive event. There is some evidence to support the idea of increased social stresses both for early-maturing girls and late-maturing boys (Angold & Rutter, 1992; Ge et al., 1996; Kaltiala-Heino et al., 2003). According to this account, the hormones themselves do not have a direct effect on depression, but they do bring about physical changes that, in turn, can cause depression-inducing stress. Yet, while indirect effects through the social consequences of early and late maturity are more feasible, these explanations, too, remain controversial. This is because hormones and physical maturation, while related, are not the same, as the initial spurt of hormones may happen for quite a while before the physical maturation is evident, thus making it important to ask about the independent contributions of these two factors. Hormones may also have other indirect physiological effects, such as increased levels of estrogen, which influence levels of the neurotransmitter serotonin, which in turn is related to depression (Hyde et al., 2008; Naninck et al., 2011).

Social Causes Social factors may also play a role in their own right. Certainly children in most cultures tend to experience major changes in their life experiences as they enter puberty. Such dramatic social changes influence both sexes, hence explaining the rise of depression in both sexes. Still, some researchers have argued that the influence is greater for girls, which can help explain the sex differences as well. For example, gender role socialization may be more intense and constraining for girls than for boys during this period (Hill & Lynch, 1983). In one study of 12,000 Norwegian adolescents, the onset of depression in girls seemed to be more closely related to perceptions about sex roles than it was in boys (Wichstrom, 1999). On a smaller scale, parenting styles also have a relation to the onset of depression in children. For example, the adolescent children of mothers who unconditionally accept their children for who they are have lower incidences of depression, while the adolescent children of mothers who are highly controlling (through such means as criticism, negative comparisons, and "guilt trips") have higher incidences of depression (Barber, 2002; Garber et al., 1997; Mandara & Pikes, 2008; see also Blatt et al., 1979, for a different view of parenting effects). The higher incidences of depression are thought to be partially produced through feelings of low self-worth in the children, but again having a shared genotype may also produce these results. The same genotype that causes girls to be depressed may cause a combination of depression and excessive control in their mothers. Surely, any social factors influencing the development of depression in childhood interact in important ways with both biological and cognitive factors.

Q: What are some explanations for gender differences in depression?

Cognitive Causes The role of cognitive patterns is one of the most intriguing explanations for the emergence of depression in adolescence and for the gender differences. For some time, researchers have proposed that people with major depression have different cognitive schemas for thinking about the world and interpreting events. For example, Aaron Beck proposed that depressed individuals have a negative style of thought that leads them to make different sorts of attributions than nondepressed individuals and that this difference in attribution style leads to depression (Beck, 1967). Beck hypothesized that depressed individuals have a mutually reinforcing set of negative beliefs about themselves, about the world, and about their future that causes a negative schema to automatically be used in most situations. A key part of Beck's approach was the idea that various biological factors, such as a certain genotype, place a child at risk and then a particular kind of stressful environment triggers the negative cognitive style. Thus, not all children with a genetic vulnerability to depression will become depressed and not all children growing up in highly stressful environments will become depressed, but when the two factors are both present, depression may emerge.

Q: How might stress and genetic factors interact to create depression?

A related theory proposes that depression grows out of feelings of hopelessness that are usually engendered by specific life experiences (Hyde et al., 2008; Rose & Abramson, 1992). A child might be ill treated, and in her attempts to figure out why, she might develop a cognitive style in which she assumes that her misfortune is because of something about her rather than about the world. When she starts to see this negative feature in global terms (that is, across many different contexts) and as stable over time, she may fall into a state of cognitive hopelessness in which her future looks very bleak. This is because she thinks that something intrinsic about her, which is very wide ranging in effects and which will always be present, will doom her to a future of negative events. This view evolved out of a theory known as **learned helplessness**, in which animals (including humans) are put in a series of uncontrollable negative situations from which they cannot learn a way to escape, leading them to "learn to be helpless." For example, a rat might be put into a cage in which it receives shocks that it can neither escape nor have any control over. When animals or people are put in these situations, they seem to learn a helpless style that is thought to be closely related to depression (Seligman, 1975).

Yet, neither of these cognitive approaches on their own can explain either the huge surge of depression in adolescence or the sex differences. We can argue that transitions during puberty result in changes in learning experiences in school, peer groups, and the like, and that girls have more stressful transitions. This links the social influence arguments mentioned earlier to tendencies to appraise many life events in more negative terms. But it is not always the case that the environments faced by teenagers are that much more stressful than those encountered a few years earlier. In fact, as seen in Chapter 15, bullying and other forms of peer aggression often reach their peak before puberty. Nonetheless, adolescence may pose its own uniquely stressful challenges, and with respect to sex differences, there are consistent reports that girls both report and actually experience more negative life events in late childhood and adolescence (Hyde et al., 2008).

We can also look beyond the impact of stressful life events on cognition and instead directly consider the child's cognitive development. Are there more general changes in how children think about the world that might be related to the surge of depression in teenagers? Such a change does seem to occur in the extent to which children are optimistic about whether current negative traits will change into more positive versions of those traits in the future. As described in Chapter 13, there is a major shift during the elementary and middle school years in how children regard the malleability of negative traits (Lockhart et al., 2002). Younger children assume that negative traits, even physical ones like missing a finger, are likely to change for the better with maturity. Older children and adults think that such change toward the positive is much less likely. In addition, younger children tend to see more of a role for their own efforts in bringing about change, hence inoculating them from learned helplessness. Children's views of the role of effort also seem to vary across cultures, which may explain the lower rates of depression in cultures such as Japan, where traits are seen as more changeable through effort (Lockhart et al., 2008).

Although a decrease in cognitive optimism may offer insight into the increase in depression in adolescence, it does not in itself explain sex differences. Future studies need to examine more systematically whether children's diminished optimistic bias as they age coincides with the onset of depression on an individual basis. As with other models, some interaction with a biological risk factor or social experiences more common to girls is also needed to explain why some individuals develop depression and others do not. It is also important to keep in mind that changes during puberty do not seem to be correlated with the rate of cognitive development during the same period (Litt, 1995). Thus, cognitive development is likely to make an independent contribution to depression that is above and beyond any direct or indirect effects of puberty (see also Lakdawalla et al., 2007).

Q: How might patterns of cognitive development explain the increase in depression with age?

Sex differences in depression during adolescence may also be related to another cognitive difference known as **rumination**. While some people respond to negative situations by problem solving or simply by distracting themselves, a third response style is to continue to think about the negative problem. People with a ruminative response style tend to mull over negative events both in the present and in the past in a manner that helps set up and maintain depressive states. That style is more common both among depressed individuals and among women than in the population at large. Women may have a stronger tendency than men to ruminate, partly because of their socialization, as girls are more likely to be encouraged to think through a situation thoroughly, whereas boys are often encouraged to problem-solve or to fix negative situations (Nolen-Hoeksema, 2003). For those who get used to this cognitive style, it can be quite difficult to change. Thus, if a group of people who tend toward depression and another group who do not are asked to think positive thoughts about themselves, the more depressed individuals are more reluctant to do so on the grounds that they are still gaining insight into themselves through the negative ruminations (Lyubomirsky & Nolen-Hoeksema, 1993). Moreover, there seem to be reciprocal negative-feedback loops in female adolescents in which rumination increases depression, which in turn increases ruminative thinking, leading to a kind of downward spiral (Nolen-Hoeksema et al., 2007). In addition, those adolescents who show more rumination about negative events are more likely to later show severe major depressive episodes than those who show lesser amounts of rumination about comparably negative events, a pattern that has led some researchers to conclude that rumination may serve to amplify the effects of negative events in ways that lead to depression (Abela & Hankin, 2011).

Even if girls are more likely to be socialized to ruminate than are boys, this still does not explain the surge of depression in the teenage years. Rumination would seem to be present in elementary school children just as much as it is in adolescents. But in adolescence, parental socialization recedes and peer influences rise, and ruminative tendencies among peers may be mutually reinforcing and rise to higher levels than at earlier ages (see New Directions in Developmental Research box).

While the etiology of all mental disorders involves an interaction of multiple factors, unipolar depression may well involve the most factors in the most complex web of interactions. Figure 16.10 illustrates one model of how affect, biology, and cognition interact over the course of development to create depression, and in particular gender differences in depression (Hyde et al., 2008). In this model, some individuals are more vulnerable, either cognitively, biologically, or emotionally in terms of temperamental traits, but in many cases the individuals may be more vulnerable in all three ways at the same time. When these vulnerabilities interact with negative life events, they together lead to what is called **depressogenic vulnerability**, which represents the convergence of all the separate factors to create depression. Unfortunately, these factors tend to be stronger in girls, and they therefore collectively contribute to the large sex difference in depression during adolescence, as shown in Figure 16.10.

Bipolar Disorder

As described earlier, bipolar disorder is marked by two distinct phases, a depressive phase and a manic phase. Although earlier views tended to see the depressive behaviors of unipolar and bipolar depression in similar ways, more recent approaches point toward some behavioral differences, including more lethargy and sleeping in bipolar disorder, as well as more changeable mood and perhaps less ruminative cognition (Bowden, 2005; Forty et al., 2008; Goldberg et al., 2008; Hantouche & Akiskal, 2005). The same approximate range of behaviors is used in the diagnosis of

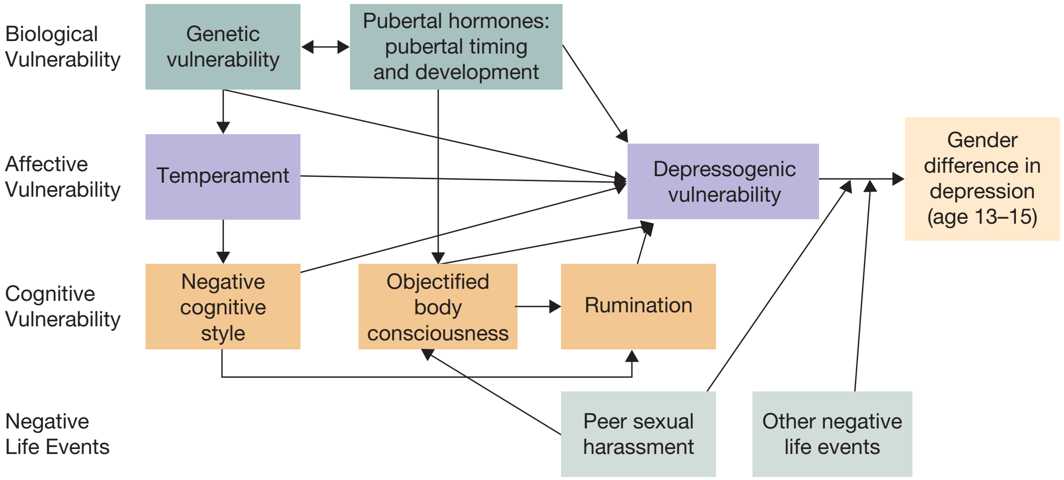

FIGURE 16.10 Factors contributing to the emergence of depression in adolescence. It now appears that biological, affective, and cognitive factors can create a high level of "depressogenic vulnerability" that interacts strongly with negative life events to create depression in adolescence and that seems to converge more strongly for girls. Adapted from Hyde et al. (2008).

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

Co-rumination, Gender, and Depression

As researchers attempt to explain the large gender difference in depression and its onset in puberty, one new variable of interest is that of **co-rumination**. Co-rumination occurs when a group tends to dwell on negative events in a mutually reinforcing manner. Like rumination, it seems to maintain and perhaps exacerbate depression, and it occurs more frequently among girls and women than among boys and men. Yet, it may seem paradoxical that girls, who are known to have generally closer and more extensive social relationships than boys, are more depressed, as social bonds are thought to normally alleviate depression (Bukowski et al., 1996). But if co-rumination is often a consequence of those bonds, it may help to explain the higher rates of depression among girls.

Co-rumination is more socially dynamic and interactive than rumination. As we first mentioned in Chapter 15, co-rumination is the excessive discussion of personal problems in one-on-one interactions with friends. These discussions may include going over the problem again and again, speculating about future problems, being encouraged by others to engage in such discussions, and focusing on negative emotions. Such discussions might be about whether a potential boyfriend is about to break up with a girl or whether a comment made by another girl is really a veiled insult (Rose, 2002). The constant discussion of problems and negative emotions might prevent vulnerable girls from thinking or acting more positively and hence might lead to or maintain depression.

When a co-rumination scale was developed, it did indeed demonstrate more co-rumination among third, fifth, seventh, and ninth grade girls than among boys, with the gender difference much larger among the adolescents in the group (Rose, 2002). Questions still remain about why co-rumination occurs more among girls in the first place. Is it simply a natural outgrowth of girls' tighter social relations and higher levels of self-disclosure? Is it a side effect of socialization differences that tend to push girls toward thinking more about internal states and personal attributions? Or does it reflect something deeper about the cognitive styles of girls and boys? Whatever the answers, the co-rumination hypothesis does suggest that girls who are depressed might be helped by interventions that focus on the social groups in which they are embedded and how the members of those social groups interact. More broadly, the social interaction patterns that distinguish boys and girls, especially shortly before and during adolescence, may be critical to understanding the emergence of gender differences in psychopathology (Crick & Zhan-Waxler, 2003).

Co-rumination may have costs by inducing depression. But it also may have benefits by promoting close friendships and networks of social support, which may help explain why it persists even with some negative consequences. Studies of adolescent girls do indeed suggest such a dual role in which co-rumination levels are associated both with higher levels of depression and with tighter social bonds (Rose et al., 2007; Starr & Davila, 2009). In addition, co-rumination seems to facilitate contagion of depressive emotions among friends (Schwartz-Mette & Rose, 2012), illustrating how the positive effects of friendships may also have negative side effects in vulnerable groups prone to co-rumination. The study of co-rumination represents a new direction of research because it takes the process of rumination beyond that of a lone individual. In considering how a social network might cause a kind of positive feedback that increases the depressive effects of rumination while also being reinforced by the ways in which it builds social bonds and mutual support, researchers can seek ways to break the loop and reduce depression.

bipolar disorder in both children and adults, except that it is necessary to adjust the ratings of such factors as "grandiose plans" for what is normal for a child of that age (Leibenluft, 2008; Leibenluft & Rich, 2008). Thus, it might not be that unusual for a fourth-grader to think that he might really become an NBA star, despite having limited athletic skills, but it would be unusual for a fourth-grader to think that he could study hard and get a college degree over the next few months.

In addition to the behavioral differences, bipolar and unipolar affective disorders tend to occur in different family groups and are reliably distinguished by different assessment instruments and by different developmental time courses, with bipolar disorders tending to emerge earlier (Leibenluft & Rich, 2008; Moreno et al., 2012). Unlike unipolar depression, bipolar disorder is not characterized by any difference between the sexes. Finally, the heritability of bipolar disorder seems to be a good deal higher than the heritability of unipolar depression. In some studies, the heritability of bipolar disorder is as high as 85 percent and averages around 65 percent (Craddock & Jones, 1999; Edvardsen et al., 2008; McGuffin et al., 2003; Potash & DePaulo, 2000; Taylor et al., 2002; Wray & Gottesman, 2012).

Causal Factors Although there is a strong genetic component to bipolar disorder, it is not so strong as to rule out other important influences. As in unipolar depression, there seems to be an important contribution from stressful life events that can both trigger the initial onset of the disorder and launch a new series of mood cycles (Post & Leverich, 2006; Rush, 2003). One study of 2.1 million Danes found clear evidence for a genetic influence based on family relatedness and a possible environmental trigger caused by the death of a parent, although the authors acknowledge a possible confound in that parents who have bipolar disorder have a higher mortality rate, and thus it could be the genetic factor that is actually at work (Mortensen et al., 2003). Children and adolescents who show deficits in the ability to label facial emotions and emotions in vocalizations may also be at greater risk for bipolar disorder (Brotman et al., 2008; Deveney et al., 2012), perhaps because such deficits lead to more stressful social interactions.

Diagnosis of Bipolar Disorder One major problem in uncovering the cause of bipolar disorder is the difficulty in diagnosing the disorder in younger children as distinct from diagnosing attention deficit hyperactivity disorder (ADHD), conduct disorders, and even schizophrenia (Weller et al., 1995). Children and young adolescents in general seem to have far more variable mood states than older individuals, and when those mood states are embedded in other disorders, they can sometimes be mistaken for symptoms of bipolar disorder. Over the last decade or so, there has been a substantial increase in the diagnosis of children, and even preschoolers, with bipolar disorder. In some cases, these may be misdiagnoses in which difficult behaviors in a child are confused with the more specific symptoms associated with pediatric bipolar disorder. If the strict criteria of the DSM-IV-TR system are used with age-appropriate adjustments for some symptoms, however, it appears that bipolar disorder can be clearly identified in quite young children, although probably not at the high levels that are often reported (Leibenluft, 2008, 2011; Leibenluft & Rich, 2008). A related diagnostic problem is that children with bipolar disorder often have several other disorders at the same time, and so the overall suite of symptoms of a bipolar child can overlap with those of children who have no bipolar component. This can create agony for parents who may hear multiple diagnoses from different professionals, each of which might lead to radically different treatments and medications. For example, if a genuine case of bipolar disorder is misdiagnosed as ADHD, several of the medications for ADHD might help launch a bipolar child into a manic episode rather than be therapeutic.

Bipolar disorder is likely to have its own developmental trajectory that is quite distinct from unipolar depression, with bipolar disorder emerging earlier and with different symptoms even in the depressive state. The developmental trajectory does not seem to surge as dramatically at a particular age, and the disorder has even been seen in preschoolers (Blumberg, 2007; B. Geller et al., 2004), suggesting that the relatively strong genetic predisposition toward bipolar disorder may result in early manifestations in childhood instead of late manifestations in adolescence or adulthood as a function of environmental stresses. Moreover, because the cases that are diagnosed very early often do show all the symptoms of a full-fledged disorder several years later, there is good reason to believe that the same disorder is involved (B. Geller et al., 2008; Wozniak et al., 2011). Indeed, in studies that develop careful assessments to distinguish the mania of bipolar disorder from other high levels of activity in children, misdiagnoses were quite uncommon (Wozniak et al., 2011). The challenge is to instill the same level of care in frontline clinicians. Finally, treatment with lithium and other mood stabilizers seems to be equally effective at all ages (Weller et al., 2004).

Q: How are the etiology and developmental trajectory of bipolar disorder different from those of unipolar disorder?

Conduct Disorder: The Case of Psychopathy

There is a huge area of developmental psychopathology that focuses on **conduct disorder**, which can be diagnosed in terms of a set of behaviors that are both aggressive and antisocial (Baker, 2009; Kazdin, 1995; Loeber et al., 2009). As seen in Table 16.3, the critieria fall into four categories: aggression against people and animals, destruction of property, theft or other violations of trust, and breaking major rules. For a child to be diagnosed with conduct disorder, he or she must show at least three of these behaviors over the course of a year. Because we have considered aggression and antisocial behaviors in other chapters and because the full scale of conduct disorders is so vast, this discussion will focus on one particular subtype—that of psychopathy, or sociopathy. We will not discuss antisocial behaviors in which there is evidence of empathy, regret, guilt, and other

Behavior Category	Specific Behaviors
Aggression against people or other animals	1. Bullies or threatens others. 2. Becomes easily engaged in or initiates physical fights. 3. Uses a weapon, such as a knife or large stick, to threaten or hurt another. 4. Is physically cruel to people or animals. 5. Has robbed another person through force or intimidation. 6. Has forced another into some form of sexual activity.
Willful destruction of property	1. Sets fires intentionally, hoping to cause damage. 2. Intentionally destroys others' property in ways other than fire.
Theft or violation of trust	1. Has broken into or entered (without permission) another's home, car, or place of business. 2. Uses lies for personal gain, such as lying about needs or obligations. 3. Has stolen items in ways that don't involve direct confrontation with the owner, such as shoplifting or using another's credit card.
Violation of major rules	1. Stays out late at night as a preteen even though parents may have strict rules against doing so. 2. Is truant from school as a preteen. 3. Has run away from home overnight at least twice.

TABLE 16.3 Diagnosing conduct disorder. Conduct disorder is diagnosed when at least three of these behaviors are present within a 1-year time interval. Adapted from American Psychiatric Association (2000).

emotions, since a different basis for these inappropriate behaviors has been hypothesized (Blair & Blair, 2009). In addition, when we consider conduct disorders as a whole, the primary focus will be on treatment methods.

Features of Psychopathy

Psychopathy is one of the most chilling disorders, and adults afflicted with this disorder often arouse highly negative reactions in those around them. For centuries, historians and writers have discussed individuals who seem to be cold, calculating, and remorseless. In 1941, Hervey Cleckley crystallized these observations in a compelling account of the disorder entitled *The Mask of Sanity* (Cleckley, 1941), which described the adult with psychopathy as having no guilt, shame, or emotional attachments, and as highly manipulative and intelligent. In essence, this characterization remains the same today, with somewhat less emphasis on intelligence as a critical factor. A person with psychopathy can be described as someone who is driven by the pursuit of goals but who does not feel the impediments of morality or empathy toward others. As such, to get to a desired end, a skilled person with psychopathy will manipulate a victim through lies, deception, and distortions.

Imagine a teenager, Harry, who "befriends" George, one of the least popular but most academically talented students in a class. Harry gives George small gifts and flatters him heavily. He finds out about George's secret crush on Mary, one of the girls in their class, and he tells George that he knows Mary. He then shows George some alleged excerpts from Mary's diary that he says he accidentally found and which say nice things about George. A few days before a critical take-home final examination, Harry asks George for help on the exam, a clear violation of the honor code. When George objects, Harry downplays the moral issues and reminds George that he did look at Mary's diary. In a veiled threat, he asks George if helping on the exam would be as embarrassing as everyone knowing that George looked at Mary's diary and had a secret crush on her. George ends up helping Harry on the exam. Since Harry has no further use for George, he stops interacting with him and, to relieve boredom, writes an anonymous e-mail telling the entire class about George's crush on Mary. When George confronts Harry, Harry denies involvement in a completely compelling manner that also casts George's one true friend in the class under a pall of suspicion.

It is difficult to imagine that people could behave so callously and ruthlessly to others and without any pangs of conscience, but the abundant case reports of such individuals suggest that they constitute roughly 1 percent of the general population and a much higher proportion of inmate populations. Some of the most successful people with psychopathy are so adroit at manipulating others that they are rarely recognized as having caused the pain that they inflict. It might seem that psychopathy is a disorder that could not emerge until adolescence or adulthood because of the manipulative skills involved. As seen shortly, however, the roots of this disorder appear very early, and a core deficit may well be shared between young children with psychopathy and adults with the disorder.

Diagnosis of Psychopathy

Specific assessments for psychopathy have been developed relatively recently, as the disorder was originally lumped into a much larger category of antisocial personality disorders in the DSM diagnosis system. When a specific screening device for psychopathy was developed, it became possible to recognize a highly specific disorder that differed from disorders in which people transgress against society for a wide variety of other reasons (Harris et al., 1994). There are reliable assessment instruments for diagnosing psychopathy in both adults (Hare, 1991) and children (Corrado et al., 2004; Das et al., 2009; Frick et al., 2000). Table 16.4 lists the features of psychopathy that are looked for in the most widely used child assessment, the Psychopathy Checklist: Youth Version (PCL:YV), which is used to assess psychopathy in adolescents between 13 and 18 years of age. The adult version is quite similar. One critical aspect of psychopathy is that the disorder is distributed fairly evenly among all socioeconomic groups, which tends to argue against the theory that psychopathy is completely a product of socialization (Pitchford, 2001; Rutter et al., 1998). More specifically, it has proved difficult to use differences in parenting practices to explain why some children appear to be callous and unemotional (Wootton et al., 1997).

Q: Describe some typical symptoms of psychopathy.

Item	Description
1. Impression management	Exhibits superficial charm and presents positive attributes to gain trust of others.
2. Grandiose sense of self-worth	Is opinionated and domineering and shows inflated sense of self.
3. Stimulation seeking	Is prone to boredom, seeks novelty and excitement, and enjoys taking risks.
4. Pathological lying	Lies easily and often.
5. Manipulation for personal gain	Deceives, manipulates, and cons people.
6. Lack of remorse/guilt	Does not feel guilty or care about hurting others.
7. Shallow affect	Does not feel deep emotion, but pretends to feel emotion and to care about others.
8. Callousness	Lacks empathy, views others as objects, and does not care about others' feelings and needs.
9. Parasitic orientation	Exploits others by taking their money and possessions or by manipulating others to do his work.
10. Poor anger control	Is easily offended and provoked to violence.
11. Promiscuous sexual behavior	Has many casual sexual encounters, often involving threats and coercion.
12. Early behavioral problems	Lies, steals, and sets fires before age 10.
13. Lacks goals	Has no interest in education and has unrealistic future goals.
14. Impulsivity	Acts out, may quit school or leave home on a whim, and does not consider consequences of his actions.
15. Irresponsibility	Engages in reckless behaviors and does not fulfill obligations or pay back debts.
16. Failure to accept responsibility	Blames others for his problems and does not take personal responsibility for his actions.
17. Unstable interpersonal relationships	Does not show commitment or loyalty to others and has volatile relationships.
18. Serious criminal behavior	Engages in many instances of criminal activity.
19. Serious violations of conditional release	Commits two or more violations (for example, crimes or drug or alcohol abuse) when released on probation from juvenile correctional facilities.
20. Criminal versatility	Engages in at least six kinds of criminal behavior.

TABLE 16.4 **Symptoms of psychopathy.** The Psychopathy Checklist: Youth Version rates individuals on 20 items that collectively are quite effective in identifying adolescents with psychopathy. Adapted from Dolan (2004).

The early roots of psychopathy are a matter of some controversy. Adults with psychopathy often have a history of various antisocial behaviors in childhood (Lynam et al., 2007), although some children who behave this way grow up to be normal adults (Hill, 2003; Saltaris, 2002). Are there more specific precursors to developing psychopathy? Among aggressive or antisocial children, some seem to lack a moral sense that guides their actions, show no genuine affection, and are unusually self-centered (Lynam, 1997). These children, who also tend to form weak attachments to their caregivers and peers, seem to be more likely to develop psychopathy (Saltaris, 2002). Some scholars have identified callous or unemotional traits that are indicators of psychopathy in young children (Barry et al., 2000; Frick & Ellis, 1999). Indeed, one review suggests that stable indicators of aberrant empathy and guilt can be found in children as young as 3 years old (Loeber et al., 2009). Moreover, even children under 2 years old who show disregard and lack of concern for others are more likely to show some antisocial and psychopathic characteristics in middle childhood (Rhee et al., 2013). Another study followed young children who showed strong antisocial patterns to see whether they later developed psychopathic tendencies. These children were compared to another group of children who first showed antisocial behavior as adolescents. In adolescence, the two groups' antisocial behaviors were quite similar. But as 26-year-olds, those who had been antisocial as young children were far more likely to show adult psychopathic tendencies (Moffitt et al., 2002).

Q: How might the first signs of psychopathy emerge in children?

Causal Factors

At all ages, those with psychopathy seem to share a core deficit: an inability to have empathy for the emotional states of others. While a skilled, successful person with psychopathy might be able to feign interest and pretend to care for another so as to attain some goal, the real ability to empathize and perceive others' emotional states may be severely impaired. Using the Psychopathy Checklist (youth and adult versions) and other measures, researchers have assessed whether children and adults who score high on the checklist also have specific deficits pertaining to empathy. They have found that both adults and children with high psychopathy scores seem to have a selective impairment in the ability to process sad and fearful expressions (Blair et al., 2001; Sylvers et al., 2011; see Scientific Methods box). Children as young as 9 years old who score high on psychopathy have been shown to have difficulty detecting sadness and fear in both facial expressions and verbal tones, but no difficulty in detecting happy or angry facial expressions or tones (Blair & Coles, 2000; Blair et al., 2001). Other studies, however, suggest that the deficits in emotion recognition may be broader than just for fear and sadness and may cover a wider range of emotions in both facial and vocal expressions (Dawel et al., 2012). Children with high psychopathy scores have also been shown to have greater difficulty distinguishing moral principles from social conventions (Blair, 1997), a distinction that comes very naturally to much younger children who do not score high on psychopathy (Lockhart, 1981; Turiel, 1983).

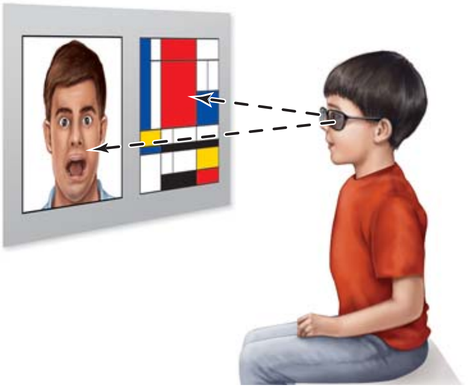
Adults with psychopathy appear to have a particular deficit in the amygdala, a brain region associated with emotional responding (Blair, 2008; Dawel et al., 2012; Laakso et al., 2001; LeDoux, 1998). Recall from Chapter 7 that the amygdala is a central part of a brain circuit concerned with processing emotional stimuli and generating emotions in response to those stimuli. For example, when adults who score high on psychopathy are asked to remember words with negative connotations, they show less activation in the amygdala than individuals who do not score high on psychopathy, as revealed by fMRI studies, but they do not show this difference when remembering neutral words (Kiehl, 2006; Kiehl et al., 2001; see Figure 16.11). Similar physiological measures also seem to be present in children who score high on psychopathy. When electrodes are used to record skin responses from high-scoring and normal-scoring children, both groups responded similarly to neutral stimuli. But when they were exposed to threatening stimuli, the high-scoring children showed much smaller skin responses than did the normal-scoring children (Blair, 1999). Using functional neuroimaging techniques (fMRI), researchers have shown that children as young as 10 years old who are callous and unemotional show reduced activation levels of the amygdala when viewing fearful facial expressions, but not when viewing angry or neutral expressions. The results suggest that children who show signs of early psychopathy may have a specific deficit at the neural level in the ability to process information related to perceiving distress in another (Jones et al., 2009; Marsh et al., 2008). A similar finding has been found in adults (Kiehl, 2006).

These neural deficits are presumably related to difficulties in emotional regulation that are often noticed in children and adults who exhibit psychopathic behaviors. Not only is there less activation in the amygdala for those scoring high on psychopathy, there is also reduced connectivity with frontal brain regions that can regulate and

SCIENTIFIC METHOD: **Psychopathy and Fear Processing**

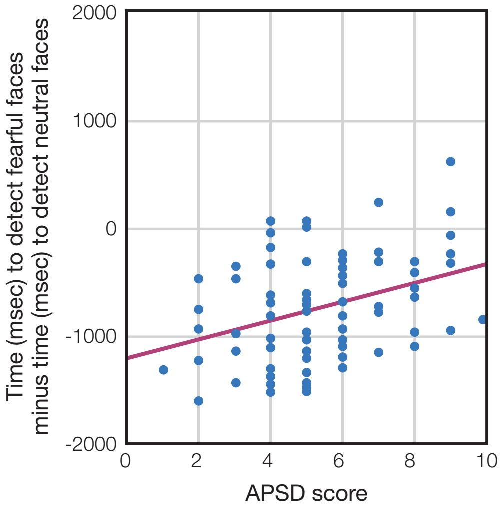
Hypothesis:

Children with psychopathic traits display fear-recognition deficits when engaging in automatic visual processing outside of their attention and awareness.



Method:

1. Researchers included in the study 88 boys, ages 7 to 11, who had often been in trouble at home or at school.
2. All boys were administered the Antisocial Process Screening Device (APSD), which detects psychopathic tendencies. Higher scores indicated more psychopathy.
3. All boys sat at a monitor while wearing goggles that quickly flashed different images to each eye. One eye saw an abstract pattern in motion that faded; the other eye saw a face (either fearful, happy, disgusted, or neutral) that also faded. The abstract pattern made it difficult to notice the faces.
4. Children were asked to press a button on the monitor as soon as they saw the face.
5. Researchers measured how quickly the boys pressed the button.



Results:

Children who had lower APSD scores noticed the fearful faces before other kinds of faces, but children who had higher scores (and more signs of psychopathy) did not.

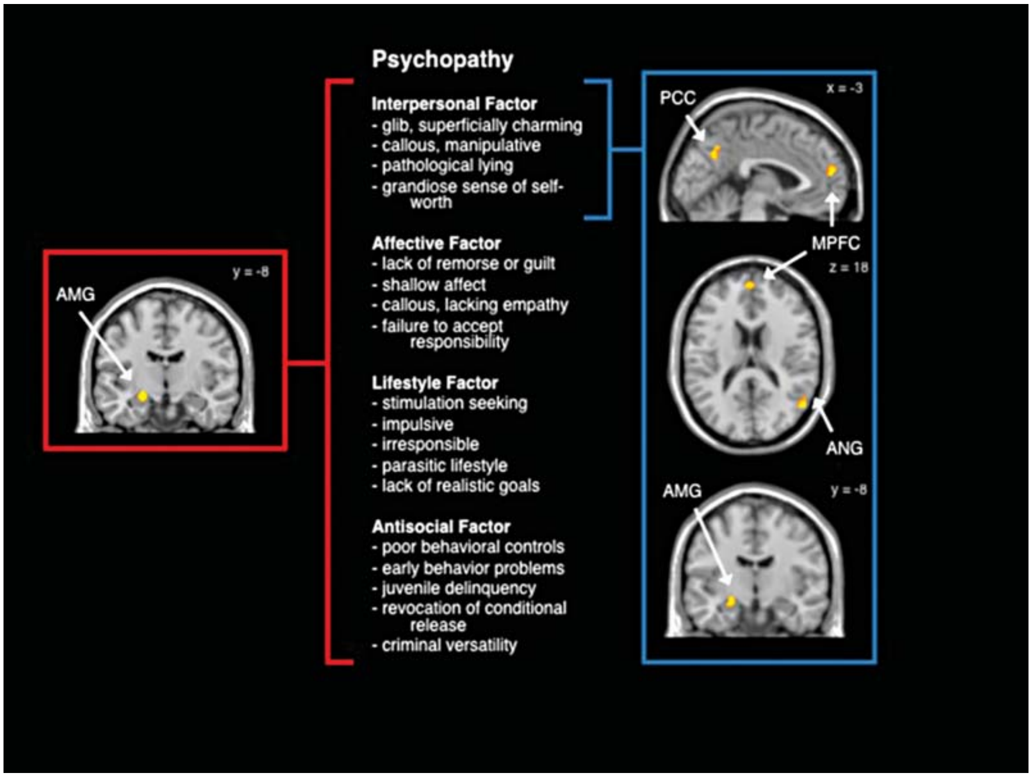
Conclusion:

Children who score high on psychopathy screening tests take longer to notice fearful faces when they are automatically processing visual stimuli that are outside of their awareness. This may be because they are not as sensitive to potential threats in their environment when they are engaged in preattentive processing of the world around them. This early automatic deficit may make it difficult to train them to be more sensitive to such expressions.

Source study: Sylvers et al. (2011).

inhibit emotions (Glenn et al., 2009; Motzkin et al., 2011; Verona et al., 2012). EEG studies of children who exhibit psychopathy-related behaviors when they are as young as 8 years old show that these children have similar difficulties in modulating negative emotions (Granic et al., 2012). Thus, it may be that early difficulties in appropriately modulating and regulating emotions interact with difficulties in empathy and emotion perception to create psychopathic behaviors.

It has also been hypothesized that there is a specific gene variant in mice that results in reduced amygdala volume and increased aggressive behavior and that it may have a counterpart in humans (Blair, 2003; Meyer-Lindenberg et al., 2006; Monaghan et al., 1997; Raine, 2008). While the heritability of psychopathy has not been studied in as much detail as the heritability of other mental disorders, there are consistent indications of genetic influences on two distinct factors, one that is concerned with impulsivity and antisocial behavior (especially of a proactive as opposed to a reactive sort) and another that is associated with callousness and “interpersonal detachment” (Bezdjian et al., 2011; Larsson et al., 2006; Liu et al., 2002; Taylor et al., 2003; Viding et al., 2008, 2012). It is not yet clear if one of these factors is more primary and tends to lead to the other or whether both contribute relatively equally to the emergence of psychopathy, but there is some sense in the literature that callousness and interpersonal detachment may be more central to the emergence of psychopathy.



Psychopathy
Interpersonal Factor
- glib, superficially charming
- callous, manipulative
- pathological lying
- grandiose sense of self-worth
Affective Factor
- lack of remorse or guilt
- shallow affect
- callous, lacking empathy
- failure to accept responsibility
Lifestyle Factor
- stimulation seeking
- impulsive
- irresponsible
- parasitic lifestyle
- lack of realistic goals
Antisocial Factor
- poor behavioral controls
- early behavior problems
- juvenile delinquency
- revocation of conditional release
- criminal versatility

FIGURE 16.11 Psychopathy and decreased brain activation levels. Brain-imaging studies repeatedly find decreases in brain activation in areas that involve the emotions when a person with psychopathy is asked to perform a task related to the emotions. Here the amygdala (left panel) shows lower levels of activation (compared with healthy controls) in individuals who have high scores in four different factors associated with psychopathy (middle panel) as well as reduced levels of activation in several other brain regions (right panel) in individuals who score high for psychopathy on interpersonal factors. In all cases, the color yellow depicts lower levels of activation relative to healthy controls. These effects have been found in adolescents as well and are thought to reflect a strong biological basis for the disorder. From Glenn et al. (2009).

In short, problems in empathy and concern for others may appear very early in development and may predict psychopathy in childhood and adulthood. Children who are unrelentingly cruel to animals and do not show any signs of remorse and who show callous disregard for others are likely to later develop psychopathy (McPhedran, 2009). One learning theory view of how this deficit results in full-fledged psychopathy works as follows: Pain or distress in others will not be a negative stimulus to a child with an empathy deficit. Because the negative event of empathizing with distress in others will not be paired with acts by the child that cause that distress, the child will not learn moral rules or other guidelines to inhibit behavior that is hurtful to others (Blair, 2003). The possibilities for intervention are discouraging. It may be that children who really cannot tap into negative emotional states of others will be exceedingly difficult to socialize in ways that build a conscience. But there may still be elements of empathy that can be identified in even the most extreme children that can then be used as targets of socialization. In addition, full-fledged psychopathy may also involve problems in inhibiting impulses and low anxiety, and these problems might be addressed through other means, including medication.

Q: What is the evidence for neurophysiological and genetic causes of psychopathy?

Schizophrenia

In many ways, **schizophrenia** captures the most popular assumptions about madness, and the earliest discussions of it often focused on the bizarre thoughts and behaviors of those with the disorder (Bleuler, 1911/1950; Kraepelin, 1919). From a developmental perspective, it is an especially intriguing disorder because it seems to occur in only a very small number of children and teenagers. Instead, it usually first appears in a person's 20s. One of the most publicized cases of a normal young adult succumbing to schizophrenia was that of John Nash, who later won the Nobel Prize in economics and was the subject of the film *A Beautiful Mind* (see Figure 16.12).

Features of Schizophrenia

Schizophrenia in adults is distinguished by a large set of symptoms that are usually sorted into three types: positive, disorganized, and negative symptoms. Positive symptoms refer to distortions or excesses of normal sensations, thoughts, beliefs, or behaviors. These may include hallucinations, usually abnormal auditory or thought patterns that are often revealed through stretches of incoherent speech, and grossly false beliefs known as **delusions**. Collectively, such patterns of positive behavior are frequently referred to as evidence of **psychosis** and often involve loss of contact

FIGURE 16.12 The emergence of schizophrenia in young adulthood. John Nash, whose brilliant work in mathematics and economics led him to be awarded a Nobel Prize, led a normal childhood and adolescence but was diagnosed with schizophrenia as a young adult and had to cope with the disease for the rest of his life.

with reality. Disorganized symptoms include more chaotic forms of speech and behavior that either make no sense or are inappropriate for a situation (such as going to the grocery store in pajamas).

Negative symptoms refer to an apparent loss of normal behaviors and traits. These may include a restricted range of emotional responses, flat affect, a lack of social responsiveness, and poor eye contact. They may also include difficulty in communicating, such as problems in answering simple questions. Finally, negative symptoms can include a loss of motivation or desire to engage in activities. A person may appear listless and may sit for long periods without any apparent desire or interest in doing anything.

Q: What are the differences between positive, disorganized, and negative symptoms of schizophrenia?

Many researchers are convinced that the core of the disorder concerns the cognitive deficits, perhaps most critically in working memory and attention (Elvevag & Goldberg, 2000; Whitfield-Gabrieli et al., 2009; Whitfield-Gabrieli & Ford, 2012). These core cognitive deficits are thought to result in positive, disorganized, and negative symptoms. There are also often motor problems and tics, unusual jerky movements, or lack of coordination. As with so many mental disorders, schizophrenia may be a cluster of several related disorders that have overlapping symptoms and causes rather than one cleanly defined deficit. In fact, Eugen Bleuler, when he initially labeled the disease, called it the "group of schizophrenias" in recognition of this possibility (Bleuler, 1911/1950).

The lifetime prevalence of schizophrenia is approximately 4 out of 1,000 (Bhugra, 2005). The disease is quite rare in children; roughly 1 out of every 40,000 cases occurs in a child under 13 years of age (Gochman et al., 2011), and most cases do not appear until late adolescence or early adulthood (Eaton et al., 1995). The obvious question is: What causes the dramatic rise in the late teens and early 20s, and why does it occur during that age period in particular? This question still puzzles researchers, as do the rare cases of clear schizophrenia that emerge much earlier in some children.

There may be two different populations of children who develop schizophrenia after childhood: those who throughout childhood seemed somehow odd, and those who seemed completely normal and were suddenly afflicted with the disease (Brennan & Walker, 2000; Neumann et al., 1995). The children who show more sudden onset are in the group that seems to be especially affected by changes in puberty. However, even in the rare cases of child-onset schizophrenia, there appears to be a catastrophic series of brain events occurring during puberty that greatly exacerbates the disease.

Unlike in cases of eating disorders and depression, it is more difficult to argue that the unique social pressures of adolescence or patterns of cognitive development are responsible for the emergence of schizophrenia during late adolescence or early adulthood. Nevertheless, stress has certainly been implicated as a possible factor in precipitating the disorder, perhaps through the effects of cortisol released on at-risk brain circuits (Corcoran et al., 2003; Walker et al., 1996, 2008). Adolescence can pose unique stresses, but a more detailed and plausible account of how such stresses could spur such a significant increase in the incidence of the disorder remains elusive. Moreover, schizophrenia tends to surge more in males than in females, a finding that is at odds with the more rapid rise in females of depression and eating disorders, both of which are thought to be related to females' experience of greater stresses in puberty (Eme, 1979; Zahn-Waxler et al., 2008).

In short, the reasons for the surge of schizophrenia in adolescence remain a mystery. No straightforward biological, social, or cognitive story has yet been well supported. More indirectly, we can look for explanations by considering the full developmental history of children who develop schizophrenia during or after puberty. Are there developmental precursors to this disease that can give us some insight into its occurrence? Although there may be different subpopulations of children who manifest the disease in different ways, this account will focus on a few general patterns that seem to hold for most cases.

Q: What is the typical developmental course of late-onset schizophrenia?

Because of the low incidence of schizophrenia, it is not very practical to closely observe a large group of children knowing that only 1 percent will end up being the group of interest. It would be much easier to take a group of people who have the disease and somehow observe what they were like as children. This idea seemed impossible until researchers realized that with the rise of video cameras and home movie systems, it has become a ritual for many families to record their children at each birthday party and other events (Grimes & Walker, 1994; Schiffman et al., 2004; Walker et al., 1993). Could information in these home movies suggest precursors of schizophrenia? Once the idea emerged, the general method was clear. A group of judges watched large collections of these home movies of children, some of whom later developed schizophrenia and some of whom did not (usually siblings of the first group). The judges, who were blind as to the children's future outcomes, coded a wide range of behaviors in the children. There were unmistakable indications of differences. In particular, children who developed schizophrenia showed more **affective blunting**—that is, less pronounced emotions as well as less frequent displays of responses indicating either strong positive or negative emotions. Thus, while those diagnosed with schizophrenia may not show the symptoms of the disorder as children, a significant number do tend to show precursor behaviors having to do with social responsiveness that may reflect social and cognitive deficits that continue to gradually accumulate throughout adolescence and beyond (Algon et al., 2012; Cannon et al., 2002; Welham et al., 2009).

Beyond social responsiveness deficits, we can also find communicative and language difficulties and some cognitive and attentional deficits (Erlenmeyer-Kimling et al., 2000; Kates, 2010; Reichenberg et al., 2010). Moreover, when at-risk children and adolescents show higher levels of unusual thought content, greater tendencies of suspicion/paranoia, and a history of substance abuse (for example, heavy use of marijuana), they are substantially more likely to later exhibit psychosis and other symptoms of schizophrenia (Cannon et al., 2008). The association of later schizophrenia with earlier marijuana use does not mean that heavy marijuana use early on causes schizophrenia, but some researchers do suspect that it may play a role in aggravating or precipitating symptoms (Anglin et al., 2012).

Other potential early signs may involve motor movement difficulties, with children who show a certain class of motor movements more likely to later develop symptoms of schizophrenia. In addition to simple delays in motor development, the unusual motor patterns include writhing and jerky movements of the limbs, unusual postures with the arms, and tics and spasms (MacManus et al., 2012). Such motor abnormalities have even been reported in infants (Walker et al., 1994).

None of these predictors, however, means that we can foretell the future of any individual child. Many children with these symptoms will not develop schizophrenia, and many people who are diagnosed with the disorder as adults do not seem to have had any history of these predictive behaviors in childhood. This raises challenges for interventions, for even if a child exhibits many predictive behaviors, we would not want to intervene in too radical a way to try to reduce the possibility of schizophrenia if the intervention itself was potentially harmful (for example, using strong medications that might have harmful side effects).

Q: What are some possible signs that young children will develop schizophrenia in the future?

Causal Factors

The genetic basis for schizophrenia has been extensively studied, and a clear relation exists between the likelihood of developing the disorder and how closely one is related to another relative who has the disorder (Cannon et al., 1998; Jablensky & Kalaydjieva, 2003). The genetic story is complex, involving several different genes and their interactions and cases where some of the genes may be present but not expressed (Claes et al., 2012; Gejman et al., 2011; Gottesman & Bertelsen, 1989).

The strong genetic component of the disease is unmistakable and might seem to suggest a purely biological explanation. But another equally dramatic finding raises further questions: roughly half of MZ twins in which one twin is diagnosed with schizophrenia do not share the disorder, even though they have identical genomes, a genetic effect that is weaker than that for obsessive-compulsive disorder (see Figure 16.13). Thus, although researchers repeatedly find higher heritabilities for schizophrenia in relatives of those with schizophrenia than in the general population, it is important to keep in mind that many adults with schizophrenia have never had any relatives who were diagnosed with the disorder (Gottesman & Erlenmeyer-Kimling, 2001). In addition, the same study that found that higher paternal age is linked to higher rates of autism in children also found a link between higher paternal age

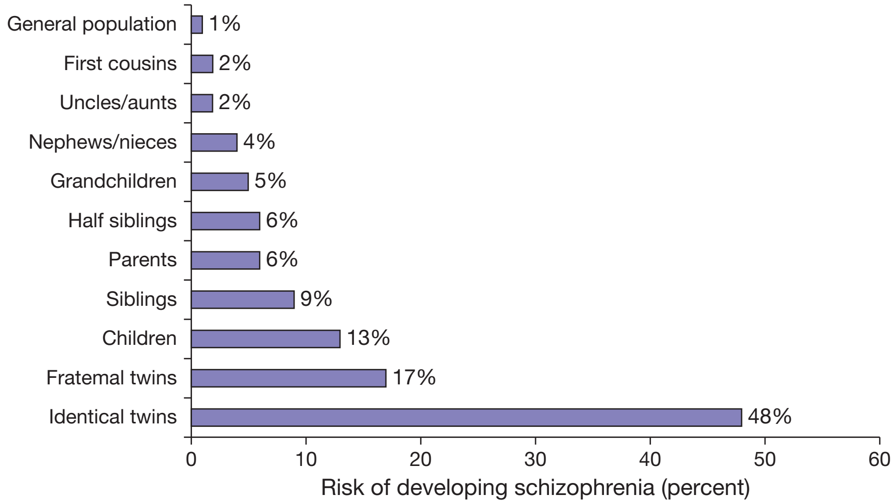

FIGURE 16.13 Genetics of schizophrenia. If an individual has schizophrenia, the odds of a relative also having the disease are closely related to the degree of genetic overlap between the two relatives. Thus, if one identical twin has schizophrenia, the odds of the other having the disease are essentially 50 percent, whereas for siblings who are not identical twins, the odds are around 10 percent. From Williams et al. (2009), based on data from Gottesman & Wolfgram (1991).

and higher rates of schizophrenia in children, apparently resulting from mutations being introduced into the child's genome when precursors of sperm cells repeatedly divided, and not because of the inheritance of mutations in either parent's genome (Kong et al., 2012).

The lack of a complete genetic predetermination for schizophrenia was most dramatically revealed in a highly unusual case of four sisters born in the 1930s. Known as the Genain quadruplets, they first came to the attention of researchers in the 1950s because one of them was showing the symptoms of a full-blown case of schizophrenia. They were all monozygotically related—hence, they had identical genes—yet they varied strikingly in the extent to which they manifested the disorder, and they continued to differ from one another at age 66, almost 40 years after they were first studied (Rosenthal, 1963; see also Mirsky et al., 1995, 2000). One sister, known as Myra, had symptoms of schizophrenia, but she was able to manage with them quite well, and she married, had children, and successfully raised a family. At the other extreme, a sister known as Hester was never able to make it on her own outside of a sheltered environment such as an institution or a home with extensive care. The other two sisters, called Nora and Iris (all are pseudonyms to protect privacy), showed moderate levels of symptoms between Myra's and Hester's.

Q: Describe evidence showing how genetic factors cannot provide a full explanation of schizophrenia.

The glaring question was: How could four genetically identical individuals have such a wide range of outcomes with a disorder that is often thought to be biologically based? The answer may lie in the details of how the disorder emerges. One account suggests that children with the at-risk gene carried by the Genain sisters will be much worse off if they contract certain infections while in the womb or shortly after birth (Rentakallio, 1997; Torrey, 1988). Since even Myra had some schizophrenic symptoms, it appears that all four sisters were equally at risk, but that differences in the severity of an early infection resulted in a difference in the extent to which the schizophrenic effects were amplified. A prenatal infection seems more plausible than a postnatal one, because that is the period during which the brain is especially susceptible to trauma (see Chapter 2).

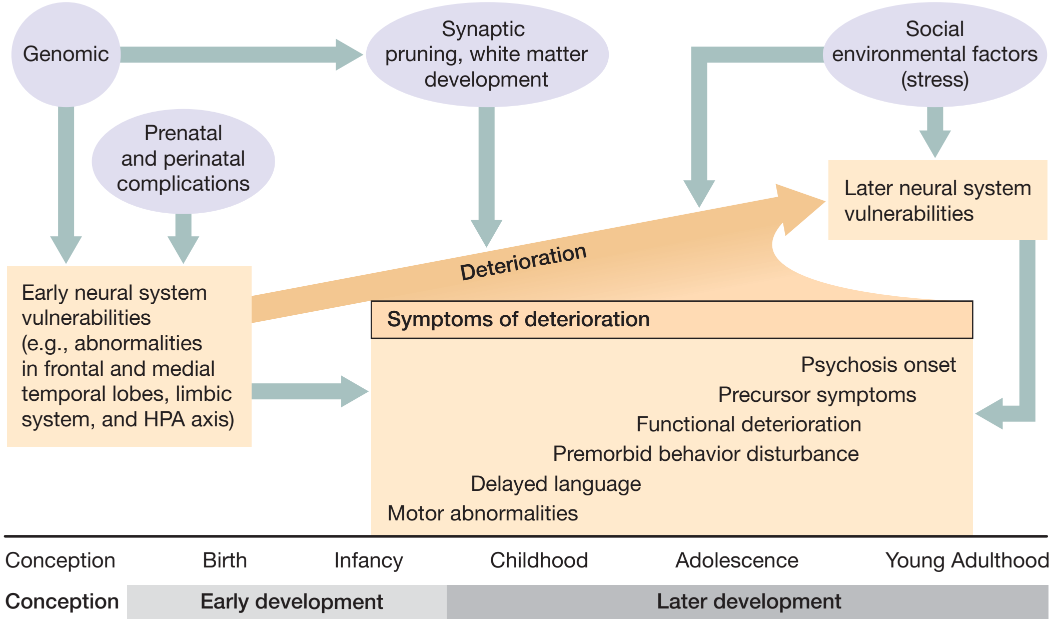
Support for the infection theory was found after the massive 1918 worldwide influenza epidemic. Following the epidemic, children whose mothers had been victims of the epidemic when they were pregnant with the child showed a higher incidence of schizophrenia (Yudofsky, 2009). In addition, the incidence of schizophrenia shows a seasonal variation based on when children are born, with schizophrenia tending to be more likely in those born in winter or spring months, shortly after periods when infectious diseases are more common (Mortensen et al., 1999). Of course, many pregnant mothers contract influenza and have children who never develop schizophrenia. Thus, some researchers have suggested that the disorder develops because of the combination of being genetically at risk and contracting an infection by a particular type of virus—sometimes called a "schizovirus"—that amplifies the genetic effects. In some cases, a particularly bad infection on its own, such as toxoplasmosis, a disease often passed to pregnant mothers by house cats, may cause schizophrenia in those who are not genetically at risk (Torrey & Yolken, 1995, 2003).

The infection theory remains controversial. Higher levels of antibodies for some viruses have been found in those with schizophrenia, but not for other viruses that are also thought to be agents that cause schizophrenia (Brown et al., 2004; Karlsson et al., 2001). Because some viruses have been known to be dormant for many years before flaring up, the infection account has also been used to explain the surge of schizophrenia in adolescence, but the mechanism remains unclear. From a cross-cultural viewpoint, some striking differences in the incidence of the disease, such as a rate that is four times higher in some regions of Ireland, have also been cited to support a model based on local disease epidemics. Taken as a whole, there seems to be an emerging consensus that exposure to influenza in the womb probably can be a contributing factor to developing the disorder (Brown et al., 2004; Yudofsky, 2009).

An alternative account argues that stress and maltreatment early on can amplify the disorder, and once again the Genain sisters may offer hints. There is some evidence that the sisters' abusive father was considerably kinder to Myra and Nora than to Iris and Hester, leading some to argue that while stress alone cannot cause schizophrenia, it can greatly amplify the symptoms (Mirsky et al., 2000). There is also the possibility, however, that Hester and Iris were treated worse because they were more impaired.

The most plausible model is one that suggests strong interactions between biological factors, such as genes and infections, and environmental ones, such as stress (Walker & Diforio, 1997; Walker et al., 2008). This "neurodevelopmental model," which emphasizes the critical influence of a biological factor during prenatal development that then gradually unfolds for many years after birth, may offer the best explanation of how the disorder gets initially launched, especially when combined with a genetic factor that makes some fetuses more vulnerable to the effects of those prenatal events (Marenco & Weinberger, 2000). One neurodevelopmental account posits three distinct times when there may be influences that increase the odds of an individual developing schizophrenia: conception, early development (prenatal and during and soon after birth), and later development (childhood, adolescence, and young adulthood).

As seen in Figure 16.14, the influences at conception are largely genetic factors that put a developing human at risk (Karlsgodt et al., 2011). Influences during early development involve both prenatal complications arising from factors such as malnutrition and maternal diseases and complications right at the time of birth, such as excessively low levels of oxygen being supplied to the baby, resulting in brain damage. These early complications may combine with certain genetic risk factors to create abnormalities in several brain regions, especially those involving the frontal and temporal lobes, the limbic system, and the hypothalamic-pituitary-adrenal axis. Later developmental factors may involve genetic abnormalities that cause excessive pruning of gray matter in frontal and temporal lobes and diminished development of white matter tracts that connect regions concerned with attention and memory. These later developmental factors are likely to be exacerbated by environmental stresses. A series of detailed MRI structural studies looking both at gray matter volume and white matter connectivity between brain regions has shown that deterioration resulting from excessive pruning of neurons and synapses and decreased connectivity often precedes the onset of full-blown symptoms of schizophrenia, strongly suggesting a causal role of these changes—that is, they are not just consequences of having the disorder (Karlsgodt et al., 2011).



Genomic
Synaptic pruning, white matter development
Social environmental factors (stress)
Prenatal and perinatal complications
Later neural system vulnerabilities
Deterioration
Early neural system vulnerabilities (e.g., abnormalities in frontal and medial temporal lobes, limbic system, and HPA axis)
Symptoms of deterioration

Adolescence
Young Adulthood
Conception
Early development
Later development

FIGURE 16.14 A neurodevelopmental model of schizophrenia. According to this model, there are three distinct periods in development: conception, early development, and later development, at which times different factors may contribute to the later onset of schizophrenia. Adapted from Karlsgodt et al. (2011).

Early-Onset Schizophrenia

For some time, scholars dismissed the presence of true schizophrenia in children. Indeed, there are serious problems distinguishing the distorted and unrealistic thoughts of a person with schizophrenia from the occasional lapses seen in many children. But as more careful measures have been introduced, including ones that look closely at cognitive abilities and distortions, researchers have identified a genuine form of schizophrenia in children (Asarnow et al., 2004; Kim-Cohen et al., 2003; Kumra & Schulz, 2008; Rapoport & Frangou, 2012; Vyas & Gogtay, 2012). Moreover, that form of the disorder shows strong developmental continuity with adult forms of the disorder, since positive, negative, and disorganized symptoms all seem to be present (Poulton et al., 2000). When schizophrenia occurs in children, it seems to particularly involve a loss of cortical gray matter in the neocortex (Rapoport et al., 1999; Thompson et al., 2001). One study compared the brains of children who had early and sustained psychosis, a hallmark of childhood schizophrenia, with the brains of both children with no signs of the disorder and children who had transient psychosis—namely, a relatively brief episode of hallucinations and other delusional behaviors. Only those in the group with sustained psychosis showed the loss of cortical gray matter, a pattern of loss that is not seen in those with late-onset schizophrenia (Gogtay et al., 2004). More focused analyses of these declines suggest that as the temporal lobes lose gray matter, there is a rise of positive symptoms, such as auditory hallucinations, and as the frontal lobes lose gray matter, there is a rise of negative symptoms, such as withdrawal. The early-onset cases are thought to end up being more severe disorders in adults and to have a stronger genetic predisposition as well as a higher incidence of relatives with the disorder (Kumra & Schulz, 2008).

In summary, schizophrenia remains a puzzling disorder with a host of causal factors that have been implicated, including genetic influences, infections, environmental stressors, and distinct periods in development when different contributing factors may dominate. The neural consequences of the disorder are, in some cases, quite dramatic and suggest that a combination of excessive pruning and diminished connectivity of brain regions may be responsible for the huge surge of the disorder in late puberty, especially among those who have already been put at risk by earlier developing factors. In the future, more sophisticated pattern recognition analyses of MRI structural information, combined with newer fMRI studies, may enable clinicians to identify with some confidence teenagers who are highly likely to soon show symptoms of the disorder (Karlsgodt et al., 2011).

Q: Compare early-onset schizophrenia with the more common case of late-onset schizophrenia.

Treatment of Childhood Psychopathologies

If this were a text on childhood psychopathology, it would be natural to discuss the treatment strategies for each disorder in turn, since they have to be tailored to the particular properties of each disease. In the context of developmental psychology as a whole, however, it is more useful to consider the general issues arising with treatment of children and to see how they apply to specific cases. The primary issue is how changing patterns of development interact with treatment. The issue concerns both normal developmental patterns and the specific patterns of development associated with psychological disorders. With respect to normal patterns of development, we can ask how, for example, cognitive development might relate to the efficacy—that is, the effectiveness—of various therapies that assume some level of information processing. With respect to the development of a disorder, we can ask whether the disorder progresses in a way that requires treatments for young children that are different from those used for adolescents or adults. These are complex issues. In this overview, we will consider some common methods of treatment in adults and whether they need to be modified for use in children, and then we will consider techniques used only with children. Some of the most common adult treatment strategies are behavioral, cognitive-behavioral, psychoanalytic, family systems, and pharmacological treatments, with frequent combinations of one or more of the first four techniques with pharmacological treatments.

Behavioral Therapies

Behavioral therapies seem to be applicable to all ages, as they are based on behaviorist principles that should work on a wide variety of animals, including people. Behavioral therapies have three major forms: classical conditioning, operant conditioning, and modeling.

Classical conditioning approaches attempt to create or extinguish a relationship between a stimulus and a response. For example, if a child has developed a fear of dogs, the therapist might attempt to expose the child repeatedly to dog images, toy dogs, and eventually real dogs in a manner that extinguishes any fear response that may have originally arisen because of a highly negative encounter with a dog (Marks, 1987; Wolpe, 1958). This technique can be effective, but it has its limitations as well. It works best for problems that have clear external triggers, such as phobias. Moreover, increased exposure to the threatening stimulus can sometimes result in a heightened fearful response to the stimulus, as opposed to extinction of the response (Zinbarg et al., 1992). More broadly, it now appears that fear conditioning may have its own unique properties and associated neural circuits that make it different from other kinds of classical conditioning, as well as from the conditioning of more general anxiety disorders (Mineka & Oehlberg, 2008). This, in turn, suggests that treatments for specific phobias might work differently from treatments for generalized anxiety, or at least that treatments might need to take into account several distinct processes that combine in different ways to contribute both to specific fears and to more general anxiety (Beckers et al., 2013).

Operant conditioning techniques, modeled after Skinner's methods, seek to shape a child's behavior in the appropriate direction through rewards and punishments (Patterson et al., 1982). These techniques have often proved successful in treating a child with a conduct disorder—for example, in treating a child who acts out frequently in the classroom or throws tantrums in supermarkets in ways that are highly disruptive and that go beyond normal childhood outbursts. A number of therapeutic programs try to use some sort of reward system with tokens that provide benefits for good behavior (Sulzer-Azaroff & Mayer, 1977, 1991). One problem concerns the finding that reinforcement schedules, while changing a behavior, can often turn the newly shaped behavior into a form of work (Lepper et al., 1973), thereby removing any intrinsic reasons to engage in the behavior and increasing the probability of it disappearing when the rewards disappear (as seen in Chapter 13, this problem often occurs when extrinsic motivations are frequently used).

A final behavioral technique uses social learning, or modeling approaches (Bandura, 1971). As we have seen in earlier chapters on socialization, this technique can effectively instill behaviors that are otherwise difficult to develop through operant conditioning. Modeling approaches have been used to reduce aggression, increase social skills, foster feelings of self-efficacy, and inhibit fear reactions, among many other targeted behaviors. For example, if young toddlers watch their mothers model positive reactions to potentially fearful stimuli, such as toy spiders and snakes, they are less likely to develop specific phobias to those stimuli when they later observe others reacting in a more aversive manner to the same stimuli (Egliston & Rapee, 2007).

Yet, all three of these approaches are affected by developmental considerations. With modeling, for example, the effectiveness of the modeling intervention is heavily dependent on a large number of variables that may in turn depend on the child's cognitive and social development. A child must be able to mentally represent the adult model's action at an appropriate level of cognitive complexity and must have a positive social relation with the model for the modeling to be effective. In tweaking all the variables of modeling to make it most effective, the therapist has to take into account every facet of social and cognitive development and thereby use very different modeling interventions as the age of the child varies.

Q: What are three different versions of therapy that are based on traditional learning theories? What are their limitations?

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) is based on the idea that a person's problems stem from how she sees and thinks about the world and how abnormal perceptions and cognitions can cause problem behaviors. Consequently, the way to change the behaviors is not simply to shape the behaviors themselves but to try to change the way the person processes and encodes information—that is, to change the way she interprets and thinks about the world around her. CBT has become the most widely used of all therapies, and it is used to treat a wide range of disorders, including depression, anxiety, obsessive-compulsive disorder, eating disorders, and even schizophrenia (Butler et al., 2006; Rector & Beck, 2001; Spangler, 1999).

First introduced by Aaron Beck as a way of treating depression (Beck, 1967; Beck et al., 1979), cognitive-behavioral therapy has a variety of techniques for helping people change their cognitive schemas. Beck identified certain patterns of thinking that were associated with depression and developed his therapy around trying to alter those cognitions. Cognitive-behavioral therapy requires active engagement and effort on the part of the patient as well as a clear goal that the patient wants to address. This alone can make it difficult to use with young children, who may not be able to identify a complex behavioral goal or who may find it hard to grasp techniques intended to change thought patterns. Cognitive-behavioral therapy tries to make a patient aware of "automatic" thought patterns that are maladaptive and tries to get the patient to recognize how changing these thought patterns would be desirable. In that sense, it requires a certain degree of metacognitive ability, the capacity to think about one's thoughts. For example, if a college student feels that he is a complete loser when he fails an exam or doesn't make a team, a CBT practitioner will try to help him see that such an extreme conclusion is not warranted and will try to guide him toward more reasonable interpretations, which will presumably make him less depressed. This technique of pointing out the irrationality of a thought or way of thinking in order to motivate change is one of the most common methods of CBT. Cognitive-behavioral therapy does not try to go as deep as psychoanalytic approaches and instead seeks to find the more immediate cognitive causes of specific behaviors and to attain specific behavior change through changing those particular cognitive causes.

Q: How does cognitive-behavioral therapy differ from more psychoanalytic approaches in the way it explores cognitive states in an individual?

CBT was designed for use with adults, so its methods need to be adjusted for use with children. Adult CBT patients are often asked to do specific "homework" exercises in which they are to try out new cognitive schemas in everyday situations. They may be asked to keep a detailed journal of their day, recording adverse situations as they arise, which increases their awareness of a problem. They may also be asked to explain or justify their distorted beliefs, and in doing so, they may recognize their inherent contradictions. Obviously, these techniques would be ineffective or impossible to use with young children.

There are several techniques to make CBT more workable with younger children. One is to engage the parents as full partners and have them work closely with their children to make them aware of alternative cognitive interpretations and to gently remind them of the problems with their distorted cognitions. By helping their children think through these issues, parents can reduce the cognitive complexity of the children's task (Albano & Kendall, 2002; Kendall et al., 2002). Therapists can also simplify the representations of thoughts by drawing cartoons for the children or by accompanying them in a difficult situation and rehearsing alternative cognitive strategies with them. The huge wave of cognitive developmental research in recent years has shown that there is far more cognitive capacity in young children when tasks are structured at their level. This can mean that if CBT is done in a developmentally sensitive manner, it can be made more easily accessible to children. As we move beyond the older views of young children as limited by stages of pre-logical thought or concrete reasoning, it seems more viable to use developmentally sensitive CBT with children (Cartwright-Hatton & Murray, 2008; Derisley, 2004).

Q: What are some challenges of using cognitive-behavioral therapy with young children?

Because anxiety disorders are one of the most frequent forms of psychopathology in young children, most CBT studies with children have focused on anxiety-related disorders. As researchers start to adjust CBT in developmentally appropriate ways, there are indications of its increasing effectiveness as a way of treating anxiety disorders in school-age children, although young children do tend to show a larger remission rate for the disorder than do older children and adults (Barrett et al., 2001; Cartwright-Hatton & Murray, 2008). CBT is now being used more broadly to treat other forms of psychopathology in children (Brent & Maalouf, 2009; Creswell & O'Connor, 2011; Hofmann et al., 2012). The challenge for the future is to more fully integrate the rapid pace of basic research on cognitive development, especially those areas related to metacognition and reasoning skills, with the techniques of CBT (Erickson & Achilles, 2004). There may also be a convergence of methods based on recent advances in using CBT to treat adults with intellectual disabilities. Traditionally, it was thought that CBT would not work with people who scored very low on intelligence tests and that classical and operant techniques would have to dominate. But with carefully tailored therapies analogous to some changes made for children, CBT can have good treatment effectiveness with that population as well (Taylor et al., 2008).

Psychoanalytic Therapies

Psychoanalytic approaches to therapy with children have a long history that goes back as far as Freud. That history has been a checkered one, however, as the efficacy of psychoanalytic approaches has been challenged by newer approaches, such as CBT. Several of the psychoanalytic approaches build on the ideas of Freud, his daughter Anna, and many others, but the area is too vast and complex to discuss in detail here. It is impressive that despite many years of sustained attacks by alternative approaches, psychoanalytic approaches retain a considerable following and are increasingly being subjected to careful experimental tests for their efficacy as well as being connected to recent research on cognitive development and attachment (Fonagy & Adshead, 2012; Fonagy & Target, 2002; Fonagy et al., 2002). One meta-analysis of almost 40 years of studies concluded that long-term psychoanalytic therapy does consistently produce positive effects in many adults (de Maat et al., 2009). Given what seems to be an emerging consensus that this form of therapy has an important role to play in treating adults, there is renewed interest in how it might be modified to be effective with children.

Family Therapies

We briefly discussed family-based approaches in the context of anorexia, when we presented Minuchin's bold ideas on the role of dynamic systems in families that fall into abnormal interaction patterns (Minuchin & Fishman, 1981). These approaches are notable because they require far more than a one-on-one therapist-child relationship; they focus on engaging the entire family. In many cases, it seems to make sense to view the child's problem as part of a full family system that has dysfunctional interaction patterns that need to be treated. Family therapy approaches have been shown to be effective on problems ranging from infant sleep patterns, to conduct disorders, to obsessive-compulsive behaviors, to depression, to substance abuse (Asarnow et al., 2001; Carr, 2009). In some cases, treating the family as a whole seems to produce larger and more enduring results. For example, in one study comparing treatments for teenagers with substance abuse problems, researchers found that while both CBT and family therapy had similar short-term effects, family therapy had better long-term outcomes, as well as being more effective for more severe forms of abuse (Liddle et al., 2008). Simply treating the child alone may not be as effective in the long term if the parents are also engaging in behaviors that tend to aggravate or even promote drug use—for example, belittling a child's competence or not providing opportunities for rich and rewarding social interactions with the rest of the family.

One major challenge of family therapy is that many members of the family often do not want to acknowledge their role in creating the underlying problems. It is all too common for parents to drop their children off at the therapist and assume that all of the child's problems are within the child and simply need to be fixed by the therapist. Even if there is some sense of a larger context for the problem, parents and therapists may not agree as to what it is. For example, in one study, researchers asked children, parents, and therapists to identify the fundamental problem or problems that they should be working on. More than 75 percent of the child/parent/therapist triads began therapy without any agreement on even a single problem that they were supposed to be working on. Even when the problem was put in the broadest terms, such as aggression or anxiety/depression, only half of the triads mutually agreed as to what the problem was (Hawley & Weisz, 2003). It is easy to see the challenges of family therapy approaches in such cases. In addition, it can take especially skilled therapists to draw a young child into a conversation rather than simply having the family and the older siblings talk about the younger child (Rober, 2008). Like so many other forms of therapy, the sensitivity and competency of the therapist is critical to the success of the therapy.

Q: What are some of the challenges of using family therapy techniques?

Pharmacological Treatments

In addition to the wide range of therapies based on interpersonal interactions, there are, of course, attempts to treat disorders directly through various medications. The steady increase in the use of drugs to treat childhood psychopathology in recent years is a vast and controversial topic (see Development and Social Policy box). Drug treatment tended initially to be for children with disorders related to ADHD and most often consisted of doses of methylphenidate (trade name Ritalin). As described in Chapter 10, the use of methylphenidate and related drugs for ADHD with ever younger children has soared, but in many cases, such drug treatment may be overused, even as it seems to have clear benefits for children who are correctly diagnosed with the disorder. At present, a much wider range of drugs is being used to treat adolescents and children (Figure 16.15 illustrates the increase in use of both stimulants and antidepressants in children and adolescents over the past few decades). In addition to drugs for ADHD, antidepressants such as fluoxetine

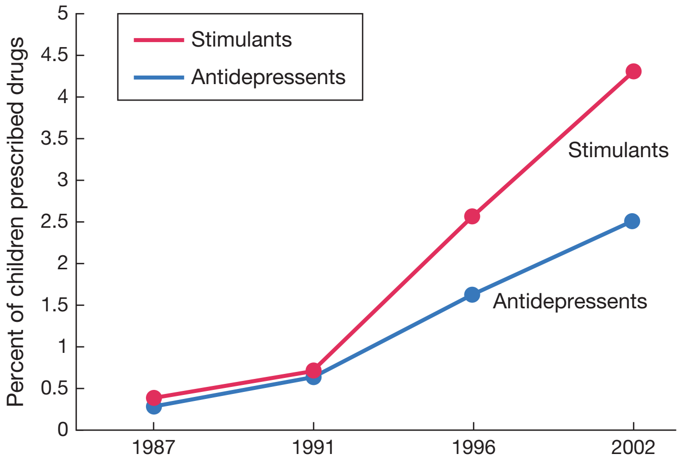

FIGURE 16.15 The rise of psychiatric drug use in children. The use of both stimulants and antidepressants by American children younger than 20 rose dramatically in the last part of the twentieth century. Although the rate of increase has slowed somewhat in more recent years, it continues to stay high. Adapted from Whitaker (2010).

DEVELOPMENT AND SOCIAL POLICY

Prescribing Psychoactive Medications to Young Children

Although most childhood psychopathologies have been treated through different sorts of therapies, in recent years drugs have emerged as a frequent form of treatment as well, a phenomenon that has generated enormous controversy (Morris & Stone, 2011; Whitaker, 2010). There has been an extraordinary rise in the use of various psychoactive medications with children, with the age for prescribing such medications decreasing to the point where even preschoolers are being given medications originally developed for adult forms of psychopathology. In fact, the fastest-growing rate of prescriptions for antidepressants is in preschoolers, with the rates of prescriptions for some groups of children tripling in the last decade (Brown, 2003; Zito et al., 2003). Over one recent 4-year period, prescription rates for preschool girls rose 65 percent (Delate et al., 2004; Warner et al., 2004), and the rates have continued to rise significantly (Parens & Johnston, 2008). It is true, of course, that these increases were from an initially very low rate, but the increases are nonetheless dramatic.

There is a lack of critical information about the risks of using such medications to treat very young children, especially over the long term. In most cases, young children are prescribed drugs that have had little or no testing of their effects in children (Brown, 2003; Hsia & Maclennan, 2009). Children are being given medications based on the results of studies conducted on adults and based on doctors' best guesses about the likely impacts and best dosages for children. But children absorb medicine at different rates than adults, and children may metabolize psychoactive medications differently than adults, which could change the drug concentrations that would be harmful in the target tissues of children. Moreover, young children might have difficulty expressing whether they are experiencing side effects from too large a dosage of a drug. All of these factors make guessing at doses a risky procedure.

When a psychological disorder is diagnosed in preschoolers, it is exceedingly difficult to know whether its causes might resemble those in an adult or older teenager, raising even more doubts about whether a particular medication designed for those groups would work in young children. Of special concern is the effect of medications taken over the long term on a child's developing brain. We have seen that there are exquisitely sensitive feedback loops between various neural circuits in development that help regulate aspects of brain growth (see Chapter 2). How might elevated levels of neurotransmitters and certain firing patterns caused by psychiatric drugs influence brain growth? At present, the answers to these questions are unknown. And even if psychoactive drugs do improve the short-term mental health of some children, it will be years before the long-term developmental implications are fully understood.

Some researchers are concerned that the welfare of children may be in conflict with the profit motive of some pharmaceutical companies (Harris, 2004). In that context, it is notable that the United Kingdom, which has a more socialized form of medicine than the United States, has much more stringent rules against prescribing antidepressants to children (Satel, 2004). The contrast between the two countries reveals how economic factors have the potential to interact with the health interests of children. These issues have become especially salient, given reports of higher levels of suicide among children taking antidepressants as opposed to placebos (Brent & Maalouf, 2009; Jureidini et al., 2004). It has even been argued that giving extended high doses of medications such as Ritalin to young children could increase the risk of tipping some children into psychotic states (Whitaker, 2010).

Some have argued that opposition to using such medications with children is "misguided resistance to appropriate treatment" (Koplewicz, 2004), on the grounds that any increased risks posed by the medications for depression, psychosis, and conduct disorders are offset by the larger risks associated with harm to the child, such as in adolescent and child suicide, or to others through violence by the child. Consider the case of depression. If it could be reliably demonstrated that prescribing antidepressants to children and adolescents does reduce the incidence of suicide, it would make it easier to evaluate the costs and benefits of such prescriptions, but no such demonstration is available (Jureidini et al., 2004; Tsapakis et al., 2008).

Parents must consider all of these concerns when deciding if their child should take psychoactive medications. When children are in a state of clear psychological distress and at great risk to themselves or others, it is inevitable that parents will have to consider the use of medications that are at least sometimes effective in bringing short-term improvements in a child's condition. Given these considerations, there is a clear need for more long-term studies of the efficacies and side effects of using psychoactive drugs in children (Rapoport, 2009).

(trade name Prozac) are commonly used for children who are either depressed or anxious, and antipsychotic drugs such as risperidone (trade name Risperdal) are used for children who have severe conduct problems and emotional outbursts as well as for some children diagnosed with ADHD (although this latter use is highly controversial).

The patterns of usage can be troubling. First, the drugs are often used "off-label," meaning that while they may have been approved for treatment of a specific disorder in adults, they may not have been approved for treatment of this disorder (or any other disorder) in children, as their effectiveness and safety in children may not have been established. Off-label usage can result in either overdosing or underdosing children and does not take into account potential long-term developmental effects (Mehler-Wex et al., 2009). Second, there are enormous variations in prescribing drugs among different populations, raising questions about the right level of use and the dangers of overprescribing. For example, prescribing antipsychotics, antidepressants, and stimulants to children is much higher in the United States than it is in the Netherlands and Germany (Mehler-Wex et al., 2009). Within the United States, children in foster care are almost four times more likely to receive ADHD-related drugs, antidepressants, and antipsychotics than children in the same socioeconomic group who are not in foster care (Zito et al., 2008). While it is true that children in foster care do have a higher incidence of diagnosed psychopathologies, it is not clear if the level of drug use is appropriate or if it reflects attempts to "manage" difficult children through medication because more social therapeutic means are less available. Comparable higher rates have also been found for children on welfare (Raghavan et al., 2012).

In many cases, it appears that psychoactive drugs in combination with one or more forms of therapy can be much more effective—especially over the long term—than any single approach used alone (Keller et al., 2000). These "multimodal" approaches may try to produce rapid change through drug treatment and then maintain the change through other forms of therapy. Such approaches do require, however, that the health practitioners involved be open to a range of techniques and not be wedded too strongly to any one method in which they may have received their training.

Evaluating Therapies

Researchers are very concerned about the need for **evidence-based therapy** with children (Kazdin & Weisz, 2003). This phrase, as well as "outcome-based therapy," is a way of simply asking that studies have been conducted showing that the therapies have proven effectiveness when used with children. It is clearly important to determine if a therapy is beneficial for children or if a drug is working at a particular level when prescribed to a child. In practice, this is much more difficult than it sounds. Many of the therapies that we have considered may be vastly more effective in the hands of a highly skilled and experienced therapist. Attempts to design large-scale experiments with such therapies frequently end up in the hands of relatively unskilled research assistants, who are often fairly young graduate students using "manualized" versions of the therapy, meaning that they try to follow what is almost a procedural cookbook. It is easy to see how much can be lost in the implementation and how flexibility and on-the-spot fine-tuning may be missing in such studies, potentially undermining an approach (Connor-Smith & Weisz, 2003). Without great care, the research could show the effectiveness of just those therapies that are the easiest to mindlessly implement without much therapist skill. No one thinks that such results would shed the best light on what really works and why. There are, however, strong economic incentives to manualize therapies as much as possible so that they can be delivered by less extensively trained, and therefore less expensive, therapists.

Despite these cautions about evidence-based approaches, it is clear that all of health care should focus on treatments with proven effectiveness and that treatment for psychological disorders should be no different. Fortunately, there are now extensive studies of evidence-based treatments, especially of CBT, that go beyond simply asking if certain programs can be easily implemented (Weisz & Kazdin, 2010). The emphasis on evidence-based treatments has resulted in welcome increases in studies with true random assignment to conditions that compare different treatments or that contrast a treatment with a no-treatment condition, and there has been more attention to replicating these studies (Kazdin, 2011). Clinicians can now employ treatments with good confidence that there is research supporting their effectiveness. There are now even several studies of such treatments' effectiveness with preschoolers (Njoroge & Yang, 2012). One remaining challenge is the need to conduct longitudinal studies of various treatments. Evidence-based studies often favor treatments that do not take extended periods, as it makes it much easier to conduct efficient studies if the researchers do not have to wait several years to assess the effectiveness of a treatment. But it seems likely that as more long-term studies are conducted, there will be some cases where more extended treatments are shown to be equally if not more effective for specific disorders. In addition, as clinicians are increasingly blending together several therapies in one program of treatment, such as combining drugs, CBT, and family therapy, there is still a need to carefully examine the effectiveness of all of these approaches in various patterns of combination, including evaluating the therapies both when used at the same time and when used one after the other.

Conclusions

The field of childhood psychopathology is so vast that it has often been viewed as a separate domain only loosely affiliated with the rest of developmental psychology. The goal of this chapter has been to familiarize readers with common childhood psychopathologies and how they emerge in development as well as to provide some basic information about possible ways to treat these disorders. As each disorder was considered, it became clear how issues in neurobiological development, social development, and cognitive development are central to understanding how and when a disorder initially emerges and how it changes over time. In turn, the problems in psychopathology pose questions that will drive future research. What sorts of cognitive capacities are needed to see contradictions and inconsistencies in one's own beliefs, and how do these capacities develop? What are the socialization patterns that might cause parents to guide girls toward more intrapersonal introspection and boys toward more problem-solving strategies? Why do these patterns exist, and how might they be related to gender differences in depression? How does the child's buoyant cognitive optimism change into the pessimism that might be responsible for the surge of depression in adolescence? These and countless other questions are coming into much sharper focus as a result of attention to psychopathology in children and adolescents. There is potential for enormous advances if the interactions of findings in these two traditional areas of psychology—developmental psychology and abnormal psychology—are explored more and more in the future.

Neuroscience is also taking on a larger role both in our understanding of the causes of psychopathology over the course of development and in devising therapeutic interventions. From an etiological viewpoint, several new technologies may start to provide converging insights. High-resolution MRI studies are uncovering changes both in gray matter, suggesting local change through excessive pruning of neurons and synapses, and in white matter, suggesting impaired connectivity between brain regions. These structural brain changes are, in turn, being linked to advanced genomic analyses that are able to track how genetic variants might be related to and even predict such changes. Epigenetic factors are also now being explored more fully, with factors ranging from stress, to infections, to use of various medications as all potentially being involved in turning certain gene pathways on or off. Neuroscience will not replace psychological models of psychopathology, but it will inform and constrain them just as psychological models will guide neuroscientific investigations.

STUDY AND REVIEW

SUMMARY

- Studying psychopathology from a developmental perspective means evaluating unusual behaviors, thoughts, and emotions that cause difficulties in functioning in terms of whether they are symptoms of psychopathology in children or symptoms that will appear as an individual grows older. It means establishing criteria for diagnosing and treating psychopathology at different ages. A developmental approach not only illuminates problems that occur in childhood, but it can help explain the nature of psychopathology in adult populations as well.

Autism

- Autism has early origins and seems to involve deficits in reasoning about the mental states of others, deficits that can have a cascade of other consequences. Usually diagnosed at 18 months, those with autism may exhibit even earlier precursor behaviors, including subtle problems with social engagement, language delays, and difficulties with joint attention. It is diagnosed four times as often in boys as in girls.
- Genetic predispositions and environmental factors, such as infections or disease either prenatally or in early infancy, have been implicated in the etiology of autism, but not certain forms of socialization.

Anxiety Disorders

- Anxiety disorders are some of the most common mental disorders in children and, in addition to specific phobias, can take the form of generalized forms of anxiety or social anxieties. Negative cognitions seem to predominate in children with these disorders and have been thought to play a causal role, interacting with genetic predispositions to anxiety. Anxiety problems in childhood generally predict long-term anxiety problems, although the source of the anxiety generally changes with age.

- Obsessive-compulsive disorder is a special form of anxiety disorder that seems to have its own distinct etiology and a strong genetic basis. The four main types of this disorder cluster around obsessions about dirt and contamination; order and symmetry; losing things and hoarding; and unwelcome violent, sexual, or blasphemous thoughts. This is a quite early-emerging disorder that may reflect a defect in an evolved safety vigilance system.

Eating Disorders

- Eating disorders emerge relatively late in development, usually in early adolescence, and tend to be far more common in girls than in boys. The three eating disorders are anorexia nervosa, bulimia, and binge eating. Adolescents with anorexia tend to be extremely thin because they intentionally refuse to eat more than minimal amounts of food, and they base their self-esteem on their thinness. Those with bulimia tend to be of normal weight or even overweight and engage in bouts of excessive eating followed by purging.
- Anorexia seems to have a more powerful genetic component than bulimia, while bulimia may be more culturally influenced. Several theories attempt to account for the gender difference and late onset but none have yet been conclusive. There does seem to be a major cognitive component to anorexia that involves distorted cognitions and/or perceptions. Some children in overprotective, conflict-avoiding families may develop anorexia as a way of exercising control and autonomy.

Depression

- Depression shows a later onset in the vast majority of cases, although clear cases of depression in early childhood have also been observed. The two different forms of depression, unipolar and bipolar, have quite different symptoms and patterns of development. Unipolar depression increases markedly in females after puberty. Bipolar disorder, which consists of shifts between depressive and manic phases, tends to occur equally in males and females, and generally emerges in late adolescence.
- The late emergence of most cases of unipolar depression may be related to changes in cognitive development, including a reduction of an optimistic bias that colors the thoughts of younger children and an increase in various forms of rumination. Unipolar depression tends to run in families, as does bipolar disorder, which has an even higher genetic heritability.

Conduct Disorder: The Case of Psychopathy

- Conduct disorder is a broad class of behavioral problems, but one severe form, known as psychopathy, is normally not diagnosed until adolescence or adulthood. People with psychopathy are extremely self-centered, are superficially charming, and do not have guilt or shame or emotional attachments that prevent them from manipulating or hurting others.
- There may be much earlier precursors of psychopathy in childhood, including difficulties in detecting sadness and fear in others' facial expressions and verbal tones. The disorder may be related to deficits in certain capacities for emotions of caring and empathy.

Schizophrenia

- Schizophrenia does not normally occur until late adolescence or early adulthood. The reasons for its late onset remain a mystery but may be related to the consequences of excessive pruning of neurons and synapses and impaired connections between brain regions that occur during adolescence.
- A very small number of cases of early-onset schizophrenia have now been documented and have been shown to be related to loss of gray matter in the neocortex. It is thought that early-onset schizophrenia, with its more devastating prognosis, may provide insights into late-onset cases as well.
- Although there are clear genetic contributions to schizophrenia, there are also striking cases where individuals with identical genes manifest the disease to dramatically different extents, making it clear that environmental factors, ranging from disease to stress, are also at work.

Treatment of Childhood Psychopathologies

- There are many ways to treat mental illness in children, ranging from classical and operant conditioning, to modeling, to cognitive-behavioral techniques, to psychoanalytic methods, to methods that work with family systems. All of these forms are still used, although cognitive-behavioral treatments, often in conjunction with medications, have become much more widespread in recent years.
- All of the treatment approaches must be sensitive to the developmental status of the child. Cognitive development, in particular, interacts heavily with the ways in which various forms of treatment might be implemented. For example, therapies that ask children to think about their own beliefs must take into account metacognitive development, and therapies that focus on family dynamics must adjust for the social and communicative abilities of the youngest members of those families.

THOUGHT QUESTIONS

1. There are several reported cases of identical (monozygotic) twins who experience very different outcomes with respect to psychopathology. Discuss a hypothetical pair of twins where one develops a serious mental illness and the other lives a life without any apparent mental illness. Consider at least three different causal factors that could be responsible for these different outcomes.

2. The onset of puberty may be related to increases in certain forms of psychopathology. Consider a form of psychopathology in which the incidence might be most related to the onset of puberty and one in which the incidence might be most unrelated. Explain your predictions in terms of potential underlying mechanisms.
3. Imagine that a 6-year-old and a 26-year-old are both referred to a clinical psychologist because of a crippling generalized anxiety disorder that is most often manifested in terms of intense anxiety when in public places. The psychologist devises two treatment programs within the cognitive-behavioral therapy (CBT) framework. Describe in detail how the treatment programs would both be compatible with CBT but at the same time be quite different because of the two ages involved.
4. A boy enters kindergarten as the youngest boy in his class and soon appears to have problems sitting still and paying attention. The teacher and the school psychologist conclude that the young boy has ADHD and strongly urge the parents to see a specialist who will prescribe Ritalin for their son. The specialist whom they recommend, a psychiatrist, agrees and suggests a medication schedule. Given that this is a very young age to start a child on Ritalin, how would you evaluate the costs and benefits of these recommendations in terms of what is best for the child? What alternatives might you consider?

Conclusions

Summary

In 1968, the U.S. Democratic Party nominated a charismatic representative from the state of Georgia, Julian Bond, as its candidate for vice president. A short while later at the party's national convention, Mr. Bond stood up and withdrew his name from consideration. At age 28, he was younger than the minimum age required for the presidency of the United States (see Figure 17.1). Based on the age restrictions for serving in the British Parliament, the U.S. Constitution states that the vice president and the president of the United States must be at least 35 years of age. Other age restrictions are placed on members of the Senate (30 years old) and the House of Representatives (25 years old). Such requirements are not unique to the United States and Great Britain. They are written into constitutions of countries throughout the world, some of which require even older ages, such as 40, for the head of state.

Why should country after country set up age restrictions for its leaders, often extending them well into middle age? In most cases, the reasons revolve around a conviction that people older than 35 or 40 years of age have better psychological qualifications for leadership roles than those who are younger. This view may seem a bit surprising at first. In many areas of cognitive functioning, there is a gradual decline after people reach their mid-20s; in tasks that measure processing speed and working memory capacity, for example, people in their 20s often outperform those who are older. But older adults may outperform younger adults in tasks requiring experience and expertise as well as more emotional regulation. Are the alleged superior psychological qualifications of people in their 40s and 50s a myth, perhaps perpetuated by older people trying to hold on to power, or are there real advantages that occur with age?

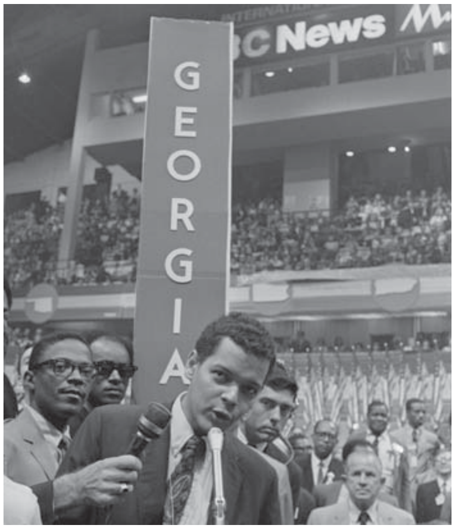

FIGURE 17.1 **Age limits on certain jobs.** On August 29, 1968, at the Democratic National Convention in Chicago, 28-year-old Julian Bond had to decline the nomination to be vice president of the United States because, according to the U.S. Constitution, a candidate must be at least 35 years old to be suitable for the presidency or vice presidency.

In this chapter, we will explore psychological changes that occur after adolescence, recognizing that psychological development is a lifelong process that is not arbitrarily cut off at the end of adolescence. We will also consider a somewhat different approach known as the life course perspective, which emphasizes key transitions that occur in various social contexts. More broadly, we will explore how we change physically and psychologically after young adulthood and how others view and respond to those changes. We will also ask what factors can explain these changes and whether individual differences in personality and intelligence stay relatively stable with increasing age. We will consider whether age groups as a whole shift in the degree to which they exhibit certain kinds of personalities, but we will also examine the enormous variation in how people age, ranging from **successful aging**, in which people seem to thrive until very late in life, to **pathological aging**, in which people decline very rapidly starting in their mid-60s. In a related vein, we will consider whether certain lifestyles and daily activities might influence the quality of aging. Finally, we will ask if there are adult "stages" of development and, to the extent that there are, whether they reflect internal changes in the maturing individual or changes dictated by the individual's changing role in society. We will also consider whether cultural influences can change the whole meaning of what it means to be old. One key message throughout the chapter is that despite clear signs of the decline of some basic physical capacities, many cognitive capacities do not decline with age and can even develop further in the elderly. Similarly, when personality changes do occur, such as a greater ability to inhibit impulsive behavior with increasing age, they often are changes that would widely be considered desirable.

Physical and Physiological Changes in Adulthood

The health and lifestyle of older adults continue to improve as researchers discover more about the process of aging and find medical treatments and adaptive strategies that enable people to cope with age-related changes more effectively. People born in the mid-nineteenth century were considered old when they were in their 50s, and most people of that age had chronic disabilities. People born in the 1920s mostly lived past 60 without developing serious or chronic diseases, but they then showed a marked increase in disease and infirmity starting in their 60s. People born in the 1980s, however, are considered to have a 50-50 chance of living to 100 and being highly active, fit, and healthy into their 70s (Fogel, 2005). In addition, there is more variation than ever in aging patterns as people engage in behaviors that result in either highly successful aging or unsuccessful aging. Positive behaviors include healthier diets and eating patterns, physical and cognitive exercise, building networks of social support, and avoiding excessive amounts of stress (Jeste et al., 2010). For these reasons, discussions of patterns of aging are a moving target, and most readers of this text are likely, with appropriate behaviors, to live longer and be healthier than even those born in the 1980s.

Despite the many ways in which older adults are healthier and living more vigorous lives than ever before, most physical and physiological measures show a continuous pattern of decline from the mid-20s onward. Muscle mass and strength gradually decline throughout middle age, and the rate of decline accelerates in later years. From age 45 on, muscles decrease roughly 15 percent in strength each decade (Frontera et al., 1991; Hughes et al., 2001). A typical, active 25-year-old may have a total muscle mass equal to 30 percent of body weight, while a typical 75-year-old may have a total muscle mass equal to only 15 percent of body weight, with men losing muscle at a considerably faster rate than women (Murton & Greenhaff, 2009). At the same time, however, muscle endurance—that is, the ability to repetitively engage in a task over a long period of time—declines much more slowly. This is evident in the much longer careers of long-distance runners and cyclists as opposed to sprinters, whose performance is more dependent on strength (see Figure 17.2). Fast-twitch, or type 2, muscles also tend to decline more quickly than slow-twitch, or type 1, muscles. The loss of endurance is also thought to reflect loss of mitochondria—the "energy factories" of the cell—in muscle cells (Holloszy et al., 1995). At the same time, however, the effects of muscle atrophy can be reduced to a remarkable degree by increased levels of exercise, especially in resistance training (Koopman & van Loon, 2009; Yarasheski, 2003).

FIGURE 17.2 Relative sparing of endurance-related muscles. While muscles related to sprinting and other explosive rapid movements tend to decline quite noticeably throughout the 20s, muscles related to longer-lasting activities can be highly effective for many more years, as seen when 37-year-old Meb Keflezighi finished fourth in the 2012 Olympic Marathon.

Q: What aspects of muscle function decline most with age?

People decrease in height as they age, as the vertebrae in their backs become more compressed (Rothman & Simeone, 1982). The skin becomes less taut and consequently more wrinkled, apparently becoming thinner and losing fat and collagen content (Newcomer & Young, 1989). Aging adults may also show osteoporosis, in which calcium depletion in bones leads to a drop in bone density and some skeletal deformities after age 50, especially in women. The onset of menopause and the sharp drop in related hormones cause the accelerated decline in bone density in women. Interestingly, humans seem to be one of the very few species that undergo menopause, leading to speculation that there may have been evolutionary pressure to stop fertility in older females because of their increased risk of dying in childbirth, which would then make them unavailable to care for older children and grandchildren (Diamond, 1996).

Almost all organ systems show some degree of decline. The kidneys show a decline in the ability to filter blood and excrete urine. The heart muscle weakens and loses capacity, and there is a drop in peak heart rate. The ability to circulate blood also declines as the arteries become more clogged. The lungs lose some capacity. The basic rate of metabolism also tends to decline, and as many middle-aged people painfully notice, their dietary intake must be cut back accordingly or their weight will increase (Cristofalo & Adelman, 2002; Tallis & Fillit, 2003).

Q: Describe three different patterns of physical change in the body that occur later in life.

Just as their organ systems decline with age, older adults also experience a pattern of decline in aspects of their brain and sensory receptors. The actual size of the brain decreases with age, losing as much as 10 percent of its weight and volume by the time a person reaches roughly 70 years (Cristofalo & Adelman, 2002; Scahill et al., 2003; Tallis & Fillit, 2003). There are also decreases in volume in many

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

Why Do We Age and Why Do We Live as Long as We Do?

A basic fact of human life remains a mystery: Why do we age? Why don't we reach a peak adult form and then simply maintain that form for perpetuity, constantly replenishing damaged tissue in the same manner that a salamander regrows its tail? One long-accepted theory argues that aging is an evolved trait in which organisms are programmed to gradually die after they have created viable offspring so that they can make resources available for the next generation (Weismann, 1889). More recently, the idea of evolutionarily programmed aging and death has been discounted as implausible when considered in detail (Kirkwood & Cremer, 1982; Sutphin & Kennedy, 2009), but the original proposal illustrates how the overall question of how and why we age is one of the most central questions in biology and one that is still not well understood. More current views argue that aging is a side effect of the lack of natural selection for repair mechanisms of tissue damage occurring later in life (Partridge, 2010).

Average lifespans vary considerably across organisms and are certainly related to their genetic makeup. It has been possible, for example, to selectively breed species of worms (Kenyon, 2001) and fruit flies (Landis et al., 2004) to obtain "Methuselahs" with far greater lifespans (for example, 75 days in fruit flies rather than 40 days). Such a genetic involvement, however, should not be taken as evidence for a genetic program that specifically triggers aging. It simply means that the factors that contribute to aging are partially related to an organism's genetic makeup.

Several distinct theories of aging remain under debate. One posits a gradual accumulation of negative random events, most often as a product of metabolic processes such as oxidation, which can leave by-products that decrease the efficiency of proteins and metabolic structures such as mitochondria.

A second view argues that cells can divide only a limited number of times, roughly 50 in many cases. This cell division limit is known as the **Hayflick limit** (Hayflick, 1965, 1998). It is thought to be related to DNA sequences called **telomeres**, which are located at the ends of chromosomes and protect the chromosomes from deteriorating and from fusing with other chromosomes. Telomeres prevent the loss of critical base pair sequences at the ends of the chromosomes during cell division by acting as protective caps to these base pairs. Because duplication of base pairs cannot occur at the extreme end of the chromosome, essential base pairs would be lost if the base pairs of the telomeres were not there. But some of the base pairs of the telomeres are not reproduced, and so the telomeres become a bit shorter with each division, sacrificing themselves to save the more critical base pairs. Ultimately, they will become too short and will lose their functional roles, although at least some cells in the body, as well as cancer cells, seem to have a mechanism for re-extending the telomeres through an enzyme known as **telomerase** (Hastings et al., 2004; Klingelhutz, 1999; Rubin, 1998). Recent work also suggests that high-stress environments, either physiologically in terms of poor nutrition or psychologically in terms of adverse events, may accelerate the rate of telomere shortening (Effros, 2009, 2012; Epel, 2009). More optimistically, some hypotheses suggest that more benign environments may halt and even reverse the effect and cause telomere lengthening and slower aging (Effros, 2009; Epel, 2009). This work has led to proposals that telomere length might be seen as a **psychobiomarker**—a biological feature that serves as an indicator of psychological functioning—of the quality of aging (Epel, 2009).

We can also see how the full life cycle becomes relevant to the effects of shortened telomeres. Thus, it may be that stress very early in life starts to prematurely shorten telomeres. One study of chick embryos showed that injecting the eggs with hormones related to stress responses resulted in shortened telomeres when the chicks were born (Haussmann et al., 2012). In humans, children who suffer from maltreatment also show shortened telomeres compared with controls (Price et al., 2013). There are even reports that children from lower socioeconomic groups have shortened telomeres compared with more affluent children, with calculations that the shortening is "roughly equivalent to 6 years of additional aging" (Needham et al., 2012). If supported by further research, these reports suggest that without amelioration later, earlier negative life experiences could have negative effects on aging half a century later.

A third view suggests that the genetic material itself, the animal's DNA, becomes slowly degraded over time through mutation and other events, such that it becomes more and more likely to produce nonoptimal proteins. If this third view is correct, the greater longevity of some species, such as humans, may be related to the higher incidence of redundant strings of DNA, which can provide a kind of backup production of critical proteins (Morrish et al., 2002).

Why do women live longer than men? The difference is quite dramatic, and ever more so with increasing age, as seen in Figure 17.3. There are a host of potential proximal causes, such as differences in hormonal influences on various body tissues, but the larger question remains whether there is any sort of adaptive reason for women to have longer lives. One evolutionary theory is based on the idea that women have more certain knowledge that their offspring are truly theirs, and therefore they have more reason to be fully invested in their offspring for the long haul so as to maximize the transfer of their genetic material to future generations (Perls & Fretts, 1998). Men, especially in societies of thousands of years ago, had far less certainty about paternity of any potential offspring and thus less of an investment in continuing care.

Genetic breeding studies with species such as worms and fruit flies may provide powerful new insights into questions of why we age and why there are sex differences in that process. These species are used because their life cycles are relatively short, allowing for relatively quick breeding. As the genomes of these species become available and as researchers come to better understand the precise roles of genes and gene pathways, the reasons for differences in aging may become clearer, as well as the possibility, someday, of gene therapy for aging humans. Unfortunately, those species that are optimal for this kind of research because of their short life cycles tend to be very different from humans, making implications for humans highly tentative and speculative. As discussed earlier, one finding that seemed to hold across a diverse range of species is that dietary restriction tends to increase longevity, and there are even some indications of such effects in humans (Partridge, 2010). Nonetheless, given the failure to find such effects in rhesus monkeys, the consequences for human aging are less clear.

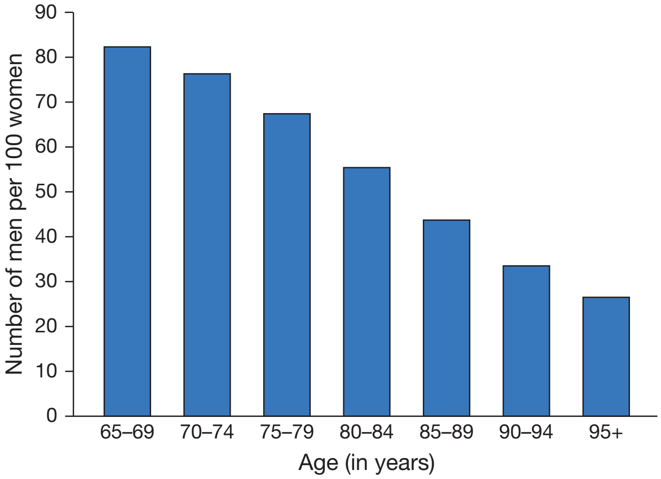

FIGURE 17.3 Sex ratios and aging. As is quickly evident at any retirement home, women vastly outnumber men in elderly populations. Adapted from the U.S. Census Bureau (1996).

FIGURE 17.4 Grandparents and the transmission of human culture. About 30,000 years ago, grandparents may have begun to play a critical role as reservoirs of human cultural practices that they passed down to their grandchildren, thereby amplifying the effects of culture for future generations.

The flip side of asking why people age is to ask why we should survive much past the age when our own offspring are able to reproduce. In traditional hunter-gatherer societies that have existed for much of human evolution, parenthood comes in the early teenage years. Why should parents need to live much past their 30s? For hundreds of thousands of years, they may not have survived much longer than that, but comparison of the teeth of fossil populations from four successive time periods suggests that a radical shift occurred in the demographics of ages in a population about 30,000 years ago. Through careful analyses of the teeth of humans and hominins over these different time periods, it is possible to estimate the distribution of ages in a population through the degree of wear in the teeth (Caspari, 2011; Caspari & Lee, 2004). Such analyses reveal a dramatic surge in the population of older adults about 30,000 years ago. In a relatively short time interval, there were more than four times as many people living into old age. This surge in the elderly coincided with simultaneous bursts in populations and cultural complexity. There may have been a mutual symbiosis between cultural complexity and the proportion of older individuals. Cultures were able to grow in size and complexity to the extent that the collective information of that culture could be retained and passed down to the next generation. Especially in preliterate societies, the best repository of that knowledge was almost surely the elder members of those populations. Thus, the elderly served as a source of essential information that more and more complex societies could use as a foundation for further advancements (see Figure 17.4). In turn, as these cultures became more advanced, they were better able to protect and care for their elderly, thus completing the symbiotic circle. It is fascinating that this sort of dramatic change may have occurred over such a relatively recent time in the history of humans.

local brain regions (in the hippocampus, for example, which affects memory; see Driscoll et al., 2003; Jernigan & Gamst, 2005; Ystad et al., 2009), in cortical thickness, and in neurotransmitter functioning. Moreover, there are increases in incidences of brain metabolites and neurofibrillary tangles, which are signs of Alzheimer's disease but not limited to those with the disease, as such increases appear in other elderly populations as well (Salthouse, 2009).

With respect to perception, there are usually substantial declines in vision and audition with age. Acuity drops off, even with corrective lenses. One of the most pervasive and commonly noticed changes is a decline in the ability to change the shape of the eye lens to focus on near objects. The need for reading glasses and bifocals is inevitable for most people at some point in their 40s. Even the most ardent health addict who defies aging in most other respects cannot avoid the need for corrective lenses for reading. Later in life, the disorder known as macular degeneration may occur, a condition in which the central area of the retina becomes pigmented and develops thinning layers; these changes eventually cause a dramatic drop in acuity. The lens of the eye also deteriorates with age, becoming yellow and filtering out some wavelengths of light. Night vision also tends to decline, as does the ability to quickly adapt to changing levels of illumination (Hyman, 1987; McMurdo & Baines, 1988).

There are also reliable patterns of decline in hearing. As the hair cells of the inner ear, or organ of Corti, become damaged, fragile, or simply die, there is a decline in the ability to hear certain frequencies, especially high frequencies. Nerves from the hair cells also tend to diminish in number. The bones that transmit sounds into the hair cells become more calcified and less able to transmit sounds. Taken together, these factors result in a decline in the overall sensitivity of hearing, which leads many elderly people to be hard of hearing and especially to have problems with hearing higher frequencies. Some entrepreneurs have capitalized on the ability of teens and young adults to hear frequencies that are not heard by older adults by developing devices that emit very annoying high-pitched sounds that discourage teens from loitering (Delaney, 2008).

Declines in taste, olfaction, and touch sensitivity also occur, but they tend to be more modest. Unfortunately, as vision and audition are often most needed in many psychological tasks, these two areas of more extensive decline can influence task performance quite dramatically.

There are several psychologically relevant diseases that occur primarily, although not exclusively, in the elderly. These include Parkinson's disease, Alzheimer's disease, general dementia, and sleep disorders. Parkinson's disease occurs when certain dopamine-producing cells in the midbrain start to die off. Although the best-known symptoms are related to motor skills, such as difficulty walking, shaky hands, and slow movements (Jankovic, 2008), psychological deficits also occur as the disease progresses, ranging from distractibility and difficulty in planning, to memory problems, to sleep disorders, to depression (Chaudhuri et al., 2006). Finally, in still later stages, many patients come to have severe dementia. Most cases start after age 60.

Alzheimer's disease is often first noticed when an individual has difficulty solving problems or remembering recent events or confuses recent memories with earlier ones. As the disease progresses, the affected individual can have substantial mood changes, language difficulty, and loss of long-term memory. The disease develops at different rates in different individuals, but in most cases, once the disease is correctly diagnosed, few individuals live much more than 10 to 15 years. Its cause is not yet known, although it is associated with the buildup of plaques (pathological accumulations of protein fragments that collect between nerve cells) in the cortex and fiber tangles (twisted fibers of protein) within nerve cells (Minati et al., 2009). Most cases start after age 60.

Dementia is a much broader pattern of disease associated with difficulties in problem solving, attention, memory, and language, and those who have dementia may also have late stages of Parkinson's and Alzheimer's disease, as well as many other disorders. While it can occur early in life, dementia is typically found in older individuals. By some estimates, roughly 1 out of 20 people older than 65 have some form of dementia, 1 in 5 people over 80 have it, and perhaps as many as half the people over 100 have it (Mathers & Leonard, 2000). But it appears that the rate of dementia is gradually declining as the elderly engage in more adaptive aging behaviors and as treatments for various disorders improve (Manton et al., 2005; Rocca et al., 2011; Schrijvers et al., 2012).

Many people older than 60 have difficulty sleeping through the night, often waking up several times for extended periods. The reasons for this change are unclear, especially given that there is considerable variation across individuals in the extent to which sleep patterns change. It is not yet known how much of the rise in "sleep fragility" is directly related to aging or how much is due to other age-related changes. One important consideration is that all people who are sleep deprived show cognitive decline, so it may be that some of the cognitive declines that are observed in the elderly might be reduced simply by improving their sleep (Crowley, 2011).

What factors cause some people to age much more successfully than others? The answer is complex and only slowly unfolding. It might seem that genes would strongly predict longevity, but their contribution, while significant, is certainly not the entire story. Thus, even monozygotic twins can show considerable variation in aging rates, although the rates are more correlated in MZ twins than in strangers (Talens et al., 2012). In addition, it is proving exceedingly difficult to isolate specific genes that may be predominantly responsible for aging effects (Barzilai et al., 2012).

There has also been a great deal of interest in the effects of diet on aging, especially in the effects of restricted diets. In several other organisms, such as rats, a restricted diet far below the normal level of intake (from 10 to 40 percent less) is associated with living substantially longer (Messaoudi et al., 2006). Nonetheless, this finding may not hold for humans—a disappointment to those who have restricted their diet in the hope of living longer. When researchers studied rhesus monkeys, a primate closely related to humans, they found no extension of life as a consequence of caloric restriction (Mattison et al., 2012). Given the large set of studies showing diet restriction effects in other species, it may be that future studies will also start to show stronger effects in primates, including humans. But the failure to find effects in one large-scale study does highlight some of the risks of extrapolating conclusions to humans. And since a large-scale random assignment study in humans is not feasible, it may be many years before there is convincing evidence of how dietary restrictions affect aging in humans.

Q: Describe four different ways in which the sensory capacities and brain structure change in the last two decades of life.

Cognitive Changes in Adulthood

Given all the age-related changes in physiology, sensory systems, and brain architecture, we might expect related declines in psychological capacities. In fact, while there are certainly some declines, there are also many areas of preserved and even improved psychological performance with age. Human cognitive capacities are so flexible and adaptive that they are not that closely tethered to underlying biological changes. We will start, however, with some of the areas of cognitive decline, for these make all the more interesting the areas of preserved and improved performance. The cognitive aspects of aging have been an intensive area of research for many years. There are practical questions about the loss of cognitive capacity in the elderly. But a major problem in such investigations is distinguishing between patterns of decline in diseases that happen to be more frequent in the elderly and patterns of decline that are caused by the aging process itself. For example, Alzheimer's disease tends to occur much more frequently in the elderly, but it would be incorrect to assume that the massive patterns of psychological decline that occur in those with Alzheimer's disease are comparable to the effects of normal aging. When people in their 40s and 50s begin to forget people's names or where they left their keys, the decline is more likely directly attributed to aging.

Reaction Time and Speed of Processing

Older people appear to slow down with normal aging. It might seem that this change simply reflects aging muscles and the ability to move limbs quickly, but in fact, speed of processing also starts to decline and at a surprisingly early age. First consider reaction time. **Simple reaction time**—namely, the time it takes to respond to a stimulus, such as pressing a computer key whenever an *x* appears on the screen—speeds up from infancy on into young adulthood. But as a person approaches her third decade of life, there is a longer response time, at first quite gradually through midlife and then much more dramatically in the seventh or eighth decade of life (Cerella, 1985, 1990; Finkel et al., 2003). The decline that starts in the late 20s is reflected in those sports where a slower reaction time may mean that an athlete in his 30s is beginning to lose his edge. Tennis may be one such example.

More **complex reaction times**, such as those involving different responses, depending on various spatial and temporal configurations of stimuli, also tend to slow down with increasing age after a person is in her 20s, but this depends on the task. With novel stimuli, there is a standard U-shaped curve (Hommel et al., 2004; Li et al., 2009; see Figure 17.5). By contrast, in areas of high expertise, reaction times and speed of processing may not slow down with increasing age but may hold constant or even get faster. One classic demonstration of increasing speed with age involved a study of the speed at which telegraph operators could type out a message in code (Bryan & Harter, 1899). By chunking sequences of dots and dashes—that is, grouping them into hierarchically organized clusters—expert telegraphers were able to achieve levels of speed that were far more related to their years of experience than to their age. Nonetheless, less expertise-laden measures of processing speed generally do decline with age, with differences in the rate of decline partially influenced by genetics, as shown by research that has found that MZ twins show more correlated rates of decline than DZ twins (Lee et al., 2012).

Memory, Higher Cognitive Functions, and Reasoning

Declines have also been found in higher-level cognitive performance. The declines often start to occur when a person is in his early 20s and then gradually lessen until he reaches

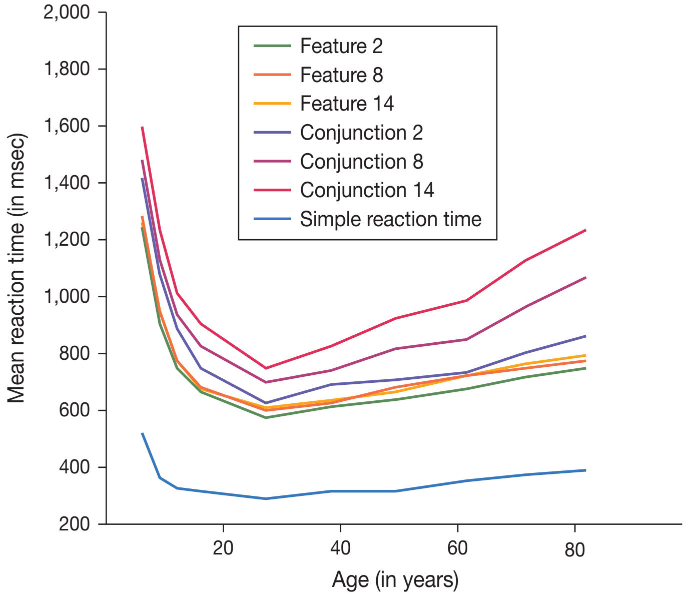

FIGURE 17.5 Complex reaction times. Reaction times in a complex task where expertise is irrelevant follow a pattern of speeding up until about age 25 and then gradually slowing down into late life. In a visual search task, adults are asked to respond as soon as they see a certain combination of features. Adapted from Hommel et al. (2004).

his mid-50s, after which point the drop can be quite a bit more dramatic (Salthouse, 2004, 2009). Figure 17.6 shows curves for four different sorts of general tasks: speed of processing, working memory, long-term memory, and world knowledge. There is a drop on the measures of speed of processing, working memory, and long-term memory. Only world knowledge improves with age, at least until the individual reaches his late 60s, and then there is only a very modest decline (Salthouse, 2004). Between the ages of 20 and 80, the drop in cognitive performance for speed of processing, working memory, and long-term memory is hardly subtle. Adults in their early 20s perform near the 75th percentile in the overall population, while those in their early 70s perform near the 20th percentile (Salthouse, 2004). Moreover, the drop occurs in roughly the same way for all healthy aging adults and is not caused by a small subset of the population afflicted with such age-related diseases as Alzheimer's (Deary et al., 2009). These differences in performance on cognitive tasks have sometimes been described as the difference between fluid and crystallized intelligence (Cattell, 1987), where fluid tasks tend to be those involving reasoning and stimulus processing in novel situations with new information, while crystallized tasks rely more on

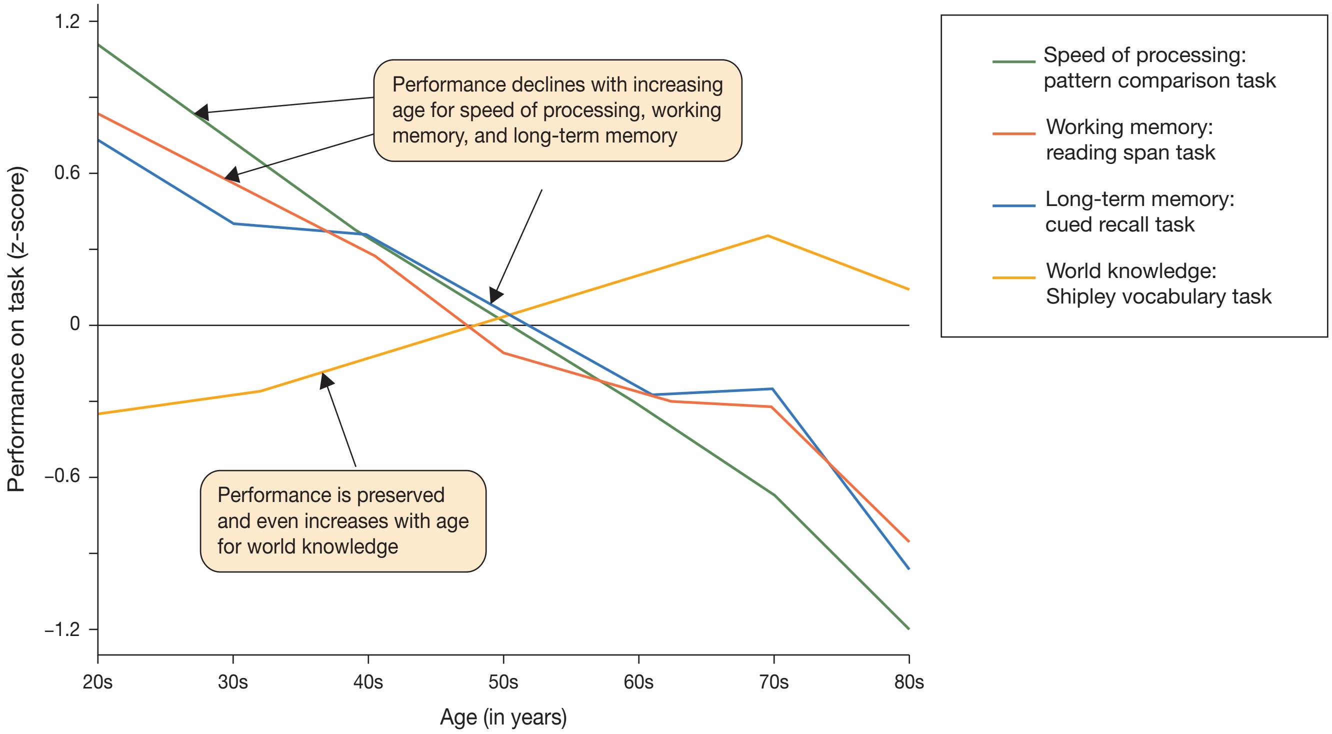

FIGURE 17.6 Fluid versus crystallized intelligence and aging. On most cognitive measures of what is considered "fluid intelligence," there is a marked decline in performance with increasing age. On measures of more "crystallized intelligence," performance can increase until a person is well into his 70s. Tasks involving speed of processing, working memory, and long-term memory clearly show declines in performance, while tasks involving general world knowledge generally show increases in performance. Adapted from Zimerman et al. (2011).

the use of information that is already available and familiar. The continuing strength of task performance relying on crystallized intelligence is a robust finding found across a wide literature (Hertzog, 2011; Palmer & Dawes, 2010; Salthouse, 2010).

In some tasks that are particularly dependent on accumulated knowledge, the hallmark of crystallized intelligence, the advantages of age can be striking. For example, the success rate on difficult crossword puzzles often continues to rise well into a person's 70s (Hambrick et al., 1999; Salthouse, 2004; see Figure 17.7). But even though they show good performance on vocabulary tests and crossword puzzles, we might expect people in their 60s and 70s to do less well on many everyday cognitive tasks, especially since 20-year-olds are in the top quarter of the population on many laboratory tasks and 70-year-olds are in the bottom quarter. Yet, older people generally do retain their competence when doing everyday cognitive tasks. Why is this so?

Q: Describe two cognitive tasks on which adults show major declines in performance with increasing age. Describe two others at which they improve.

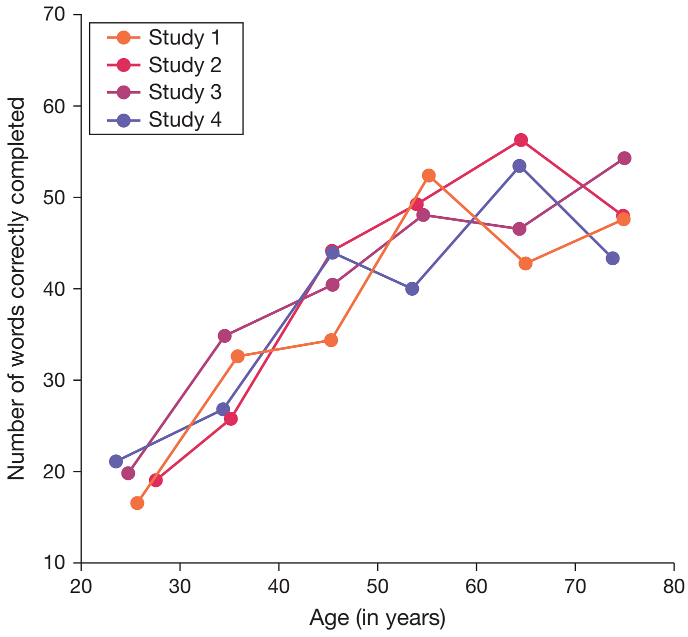

FIGURE 17.7 Consistent cognitive improvement with aging. One of the most robust examples of a cognitive skill that increases throughout the lifespan is that of solving crossword puzzles. This graph shows strikingly similar improvements across four different studies. Adapted from Salthouse (2004).

There are several reasons why people in their 60s and 70s may continue to do well on a wide variety of cognitive tasks. First, many everyday tasks, such as shopping for groceries, preparing a tax return, or assessing a cell phone plan, build on large blocks of familiar knowledge, an area where age can often be an advantage. Second, as seen in the telegraph operator example, many skills can continue to improve over time as individuals develop ever more integrative strategies. For example, even though muscle movements, reaction times, and other speed-related measures all decline starting when people are in their 20s and into their 50s, there is no decline in typing speed among expert typists (Salthouse, 1984, 1999). Indeed, in many cases, there is a continuing increase in speed well into midlife. Many skills can be more and more refined and hierarchically organized in ways that make them more efficient to produce. People often underestimate just how long it takes to become truly expert in a domain. In many areas of complex skills, such as anesthesiology, stock trading, or carpentry, it is estimated that at least 10,000 hours of full, effortful engagement in the task are needed to reach the highest level of expertise (Ericsson & Lehmann, 1996). Assuming that many people in their jobs may not spend more than 20 hours a week actually engaged in a task (such as surgery), it would take roughly 10 years to reach such a level, which after initial qualifying training is factored in, may mean that people do not reach the maximum skill level until sometime in their mid-40s.

Thus, in many areas, as people grow older, they decide to specialize in a manner that optimizes a particular niche of expertise. This means that they choose an area in which they can use the strategy of **optimization**—that is, continuing to practice over many hours to perfect a skill such as manuscript editing—and they select specific goals within that area—for example, building up world knowledge relevant to the topic areas where they do most of their editing by reading extensively about those areas. Although the upper limits of the benefits of such specializations and practice are not yet known, it seems reasonable that, in many cases, a person may be able to continually optimize performance for 20 or even 30 years. Those individuals who cognitively age in a "successful" manner may be those who develop a skill that they can continue to fine-tune and improve in decade after decade.

A different phenomenon that mitigates the effects of aging on performance may be **compensation**—using aids or altering behavior to make up for losses in cognitive or physical abilities. As people age, they may start to realize more clearly the limits of their cognitive systems and may develop ways of working around those limits. This might be as simple as learning to use a notepad to help them remember novel information or as complex as developing new networks of friends and acquaintances who can complement their cognitive shortcomings. An aging person may learn a large array of strategies for dealing with declining facets of cognition and thereby keep her performance at a high level (Bäckman & Dixon, 1992; Dixon et al., 2001; Freund & Baltes, 2002a). A general model of selection, optimization, and compensation has been proposed by Baltes and his colleagues (Baltes, 1997; Freund & Baltes, 2002b; Marsiske et al., 1995), in which successfully aging individuals learn to select tasks at which they will excel, optimize performance in these tasks, and compensate for some deficits with other skills. Baltes and his colleagues describe the particularly compelling case of the aging, brilliant pianist Arthur Rubinstein, who continued to play the piano with enormous skill well into his 80s (see Figure 17.8). When asked how he did it, Rubinstein described in detail how he picked a smaller set of age-appropriate pieces (selection), worked on them with great effort (optimization), and learned to mask loss of finger motor speed with a technique of speed contrast that gave a strong illusion of great speed (compensation).

Q: What are some reasons why certain cognitive functions stay constant or even improve in aging populations?

FIGURE 17.8 Successful aging and motor skills. Arthur Rubinstein continued to dazzle audiences well into his 80s by cleverly compensating for some slowing of his finger movements with other skills.

Skills in selection, compensation, and optimization may play a large role in the increasing ability to remember to do a task or to attain a goal in the future, which is known as **prospective memory**. Prospective memory might include remembering to pick up the dry cleaning on the way home from work or remembering to send in an absentee ballot before an election. Although performance on memory tasks generally tends to decline in the elderly, prospective memory is often preserved until very old age. Thus, as people in their 50s continue to age, their ability to remember to perform future acts may stay constant or even improve in some areas (Einstein & McDaniel, 1990; Einstein et al., 1997). One common explanation of this improvement may be that there is a robust ability for a person to monitor his cognitive performance with metacognitive and executive skills, which may continue to function well with age, perhaps especially as a means of compensating for specific areas of decline (Baltes, 1997; Einstein et al., 1997; Scullin et al., 2011). As older people start to confront the limits of working memory in more novel tasks, they may develop a clear sense of the ways that memory can fail and acquire strategies for working against such failures. Such strategies might be as simple as putting a note on a door as a reminder to do something when leaving the house in the morning or as complex as getting several friends to feel socially obligated to do an important task. These everyday strategies may help explain why older adults may show deficits in laboratory tasks of prospective memory but actually outperform younger adults in many real-life prospective memory tasks (Bailey et al., 2010; Henry et al., 2004).

Not all memory processes that involve strong metacognitive and executive processing continue to function well in the elderly. One area of decline involves failures in source monitoring (Henkel et al., 1998) and in related abilities to distinguish the frequency with which memories have been encountered from the actual instances in which those memories were experienced (Hay & Jacoby, 1999; Jacoby, 1999b). As we saw in Chapter 10, source monitoring involves the ability to tag a memory to the source or situation in which it was learned. Was it learned firsthand, through testimony of another, or through a dream? There is now considerable evidence of source monitoring problems in the elderly (Johnson & Mitchell, 2002; Mitchell & Johnson, 2009). For example, older adults are more likely than younger adults to say that they saw something that was only falsely suggested to them and are more confident of those false memories. Subsequent analyses revealed that older adults were less likely than younger adults to encode or use various cues to source information, such as perceptual cues distinguishing speakers, or context, or temporal (time-related) cues that could place information in a plausible or implausible time frame. Moreover, confidence in the semantic information (knowledge of the facts) of a message often seems to give a false confidence in the episodic information (knowing the experience and situation in which facts were learned; see Mitchell et al., 2003). It seems likely that difficulties in source monitoring are closely related to difficulties with episodic as opposed to semantic memory and with declines in function in some processing areas of the left prefrontal cortex. In a related manner, implicit memories also tend to show much less decline than explicit memories (Chauvel et al., 2012; Fleischman et al., 2004). Thus, an elderly person might learn to remember how to do a new routine in a nursing facility quite easily but not be able to remember ever having been taught the new routine.

A related problem may be a loss of the ability to distinguish a strong sense of familiarity from more episode-specific memories; indeed, some have argued that unscrupulous sales representatives prey on such disabilities to lull the elderly into a false sense of trust (Jacoby, 1999a). For example, a sales representative for a dubious life insurance policy might call up an elderly woman several times and give his name each time. The woman would not initially know his name, but over time she would come to recognize it as familiar. She might not, however, remember the context in which she had acquired that familiarity. Thus, when the salesperson called for the sixth time, she might have a reassuring sense of familiarity but no memory that the familiarity had been built up by repeated calls from a stranger. The salesperson, who would be aware of this deficit, would start to act as if he were an old acquaintance and then would make the sales pitch on that basis. The precise deficit here seems to involve a lack of explicit memories of specific events but a near complete sparing of an implicit memory that provides a strong sense of familiarity.

A different domain of cognition that often seems to be spared in the healthy elderly is that of spatial memory. When tested over brief intervals to determine their memory for at least modest-sized displays of objects in different spatial locations, the healthy elderly showed no obvious decline with age (Olson et al., 2004). Because these sorts of memory traces are often learned incidentally in real life—that is, we build a cognitive map automatically as we move through an environment—it may be that such memories are relatively spared in the same way as much of implicit memory (Pilotti et al., 2003).

In some cases, older adults can show considerably better reasoning skills than younger adults in context-rich everyday decision tasks. For example, younger adults tend to commit reasoning errors because of an **attraction effect** in which their estimates of the value of a good may vary as the result of additional information about other goods, even though that information should be irrelevant. Thus, if I know that a medium-quality radio costs $30 and a high-quality radio costs $60, my choice of which is a better buy should not be influenced by knowing that a poor-quality radio costs $15. Yet, such information does influence younger adults' decisions. As such, context affects judgments where it should not (Tversky & Simonson, 1993). When the same tasks are given to older adults, however, they make decisions in a more rational and consistent manner that is not buffeted about as much by context (Tentori et al., 2001). Moreover, older adults show this resistance to context influences not only in domains of expertise but also in unfamiliar domains, whereas college students tend to be more limited, showing some immunity to context only in more familiar domains (Kim & Hasher, 2005).

It is not completely clear why older adults should show an advantage over younger adults in decision-making tasks that are prone to attraction effects. But one possible explanation may have to do with a tendency on the part of younger adults to try to adopt analytical strategies in which each alternative is weighed carefully, setting up possible interference effects from new information. Older adults, who use more global heuristics, may not be so "attracted" to discrete new pieces of information (Kim & Hasher, 2005; Peters et al., 2000).

More broadly, it would be misleading to characterize most elderly people as easy marks for unscrupulous predators who are attempting to bamboozle them into making bad decisions. Even though there may be declines in several components of memory processing, attention, and reasoning, elderly people often do well in more complex decision tasks. In some cases, they do so by engaging in the decision-making process in a manner that minimizes the effects of any deficits, such as slowing down the decision task and perhaps writing down key points on a notepad (Yoon et al., 2009). In other cases, as shown in the case of attraction effects, the cognitive abilities of the elderly may confer advantages in certain decision tasks without the need for any real efforts to compensate for deficits (Blanchard-Fields, 2007; Healey & Hasher, 2009: Zimerman et al., 2011). Elderly adults seem to be especially adept at making emotion-laden interpersonal decisions, apparently because they are more sophisticated at regulating their emotions during decision making (Blanchard-Fields et al., 2007). Greater abilities in some of these areas may be why some governments require that elected leaders be above a certain age. In an emotion-laden crisis, a higher level of emotion regulation may be important.

Daily Activities and Cognitive Aging

Although it is clearly a mistake to see aging as a decline on all psychological fronts, most people in their later years would like to slow down, stop, or even reverse the decline of some aspects of their cognitive abilities. It has been assumed for some time that exercise and diet matter, but only recently have experimental studies shown that they affect cognitive functioning. Based on these studies, it is now clear that daily activities can make a difference.

People who exercise regularly in their later years tend to show slower rates of cognitive decline, a finding that was originally based on correlational studies (Spirduso, 1980). But it is difficult to make inferences about causation from such studies. Perhaps people who have high levels of cognitive functioning are more likely to pick exercise activities. Or perhaps people with a more positive mood choose to engage in both more cognitively challenging tasks and more strenuous forms of exercise. The causal effects of exercise become clearer when experimental studies are considered. From a large series of studies, we know that when elderly participants are randomly assigned to exercise groups and control groups, those who engage in regular exercise for as little as a few months will show better levels of cognitive functioning on tasks as diverse as simple speed tasks and complex executive functions such as planning, switching tasks, and inhibiting distracting information, with the strongest effects usually occurring for the higher cognitive and executive functioning tasks (Colcombe & Kramer, 2003; Hillman et al., 2008; Kramer et al., 2006; see Figure 17.9). At the neural level, studies with rats and mice show that regular exercise can have a dramatic effect on structures throughout the brain, not just in the motor cortex (Cotman & Berchtold, 2002; van Praag et al., 2005). In addition, there are improvements in cognitive performance in abilities associated with those brain regions (van Praag, 2009; van Praag et al., 2005). These effects are strong in older animals as well, not just in young adult animals. The mechanism seems to involve the turning on of several gene cascades responsible for nerve growth and synaptic activity (Chae et al., 2009; Cotman & Berchtold, 2002). In studies with humans, it has also been shown that those who are randomly assigned to a group that engages in aerobic exercise will not only have increases in cognitive performance but will also have increased activation levels in brain regions associated with those tasks and increases in gray matter and white matter volume in those brain regions (Bherer, 2012; Colcombe et al., 2004, 2006; Erickson & Kramer, 2009; Hillman et al., 2008; Kramer et al., 2006).

In short, simple physical exercise seems to stimulate and preserve brain systems that support both simple and complex cognitions, and it may actually slow the various forms of neural and cognitive decline that occur with aging. It is important to note, however, that the positive effects of exercise on brain function and cognition occur at all ages, so even college-age populations can show significant cognitive benefits from exercise (Aberg et al., 2009).

Diet can also influence cognitive decline. But the most dramatic influence may not be a function of what we eat as much as a consequence of how much we eat. In particular, a diet that is sharply restricted in total calories has been associated with a slower rate of cognitive decline. Again, the majority of the human studies are correlational. Lean adults tend to have slower rates of cognitive decline than overweight adults, but this may be because people with a certain level of achievement motivation are both more diligent learners and more diligent dieters. Experimental studies with healthy elderly participants more clearly show a causal influence of caloric restriction on cognitive ability. In one study with people whose average age was around 60, the group that had their daily calories reduced by 30 percent showed marked improvement in performance on memory tasks after 3 months (Witte et al., 2009). On some memory tasks, the calorie-restricted group showed a more than 20 percent

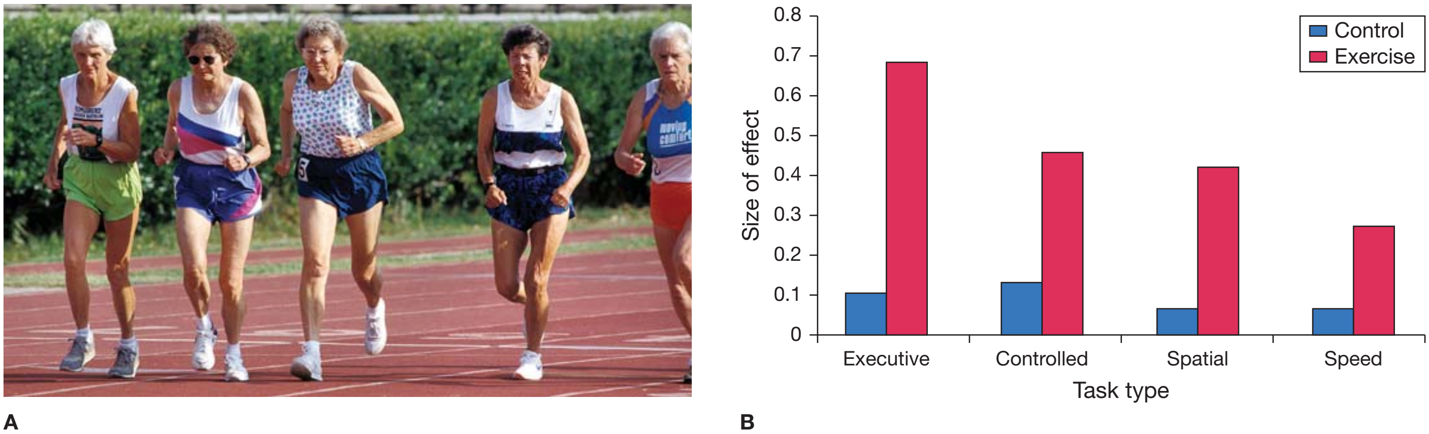

FIGURE 17.9 Exercise and cognitive aging. (A) Regular aerobic exercise has been causally linked not just to improved physiological health in the elderly but also to improved cognitive performance. **(B)** In older adults, exercise is strongly associated with higher scores on a variety of cognitive tasks, with the strongest effects occurring on executive tasks and more modest effects occurring on speed-of-processing tasks. These effects are found not only in correlational studies but also in experimental studies that randomly assign elderly individuals to exercise groups and control groups. This graph summarizes a meta-analysis of a large set of such studies. From Hillman et al. (2008).

increase in performance when compared with controls who did not have their diets restricted. The reduced calories may work through changing insulin levels that lead to increases in synaptic connections and protection of neurons in the brain (Witte et al., 2009).

Q: What aspects of cognition are influenced most by daily exercise?

It has long been thought that there is a "use it or lose it" rule that governs cognitive aging, because those who stay more cognitively active show slower rates of cognitive decline (Hultsch et al., 1999; Schaie, 2008). Many older adults who believe in this rule will engage in regular cognitively challenging activities such as word and card games as a form of cognitive calisthenics. Again, random assignment training studies are the best way to make strong inferences about causality. Here the findings are complex but point toward the need for a good deal of specificity in the training. Thus, if a group of elderly people practice daily on a certain activity such as a video game, they will show improvements in that game and in closely related tasks but generally not in other less similar cognitive tasks (Mather, 2010; Rabipour & Raz, 2012).

Some accounts of the sparing of cognitive functions in the elderly refer to the idea of "cognitive reserve" (Stern, 2009). **Cognitive reserve** is the idea that some people have more brain capacity to begin with and thereby have more brain structures "in reserve" to support functioning in the face of aging-associated decline or minor brain injuries. They may also have richer links between memories, thereby allowing the memories to more robustly reinforce each other. There is good evidence that people with above-normal cognitive capacities in college and middle age do tend to show higher levels of cognitive functioning in old age (Stern, 2009), but it is not yet known if cognitive reserve is the primary reason or if people with higher levels of cognitive ability remain active on many fronts and thereby maintain their abilities through activity, not because of reserves.

One study of young and old college professors and young and old people selected from a more general population documented less decline in the older professors than in the general population, but also found interesting differences across tasks. Simple speed tasks, such as tasks involving one-choice reaction times, showed similar patterns of decline in the elderly professors and among the elderly in the general population. With more cognitively complex tasks, however, such as recall of a prose passage, the elderly professors showed almost no decline in performance, while the elderly people from the general population showed a dramatic decline (Shimamura et al., 1995). The finding of a decline in simple speed tasks tends to suggest that a cognitive reserve explanation cannot be the whole story, since the reserve might be expected to reduce decline in those areas as well.

Q: What contrasting roles do implicit and explicit memories seem to play in aging populations?

Circadian Rhythms, Cognition, and the Lifespan

Circadian rhythms—that is, the shifts in biological activity and functions throughout a daily cycle—typically vary in college-aged people and middle-aged people. Most college students seem to be more alert and cognitively functional in the late afternoon or evening, while most middle-aged adults seem to be "morning people" (see Figure 17.10). Interestingly, children also tend to have peak performance earlier in the day, but a shift toward peak performance later in the day happens rather rapidly around puberty. As people

FIGURE 17.10 Time of day and cognitive functioning. Although many college students may find that they study best late in the afternoon or in the evening, older adults tend to be more effective cognitively in the early morning and can show marked drops in performance in the late afternoon, often taking naps on purpose or simply falling asleep unintentionally wherever they are.

progress into middle age and beyond, however, they seem to shift back to the morning as the time of day when they do their most productive and challenging intellectual work. This shift might reflect the ways in which adults take on the habits of the workplace, where productivity in the early hours may be a critical part of a business. Or the causation may operate in the opposite direction, with the workplace hours of middle-aged individuals reflecting the optimal time of day for being most productive. Support for this second interpretation comes from a wide variety of studies in both humans and animals in which the optimal period for complex tasks has been shown to gradually shift toward earlier and earlier times of the day as organisms age (Hasher et al., 1999; Martin et al., 2008; Winocur & Hasher, 2002).

Moreover, the shift does not seem to merely reflect increasing fatigue over the course of the day in older people. Instead, people's daily circadian rhythms, which reflect 24-hour cyclical surges of a large number of hormones, and changes in neurotransmitter functions and physiological patterns, shift with respect to the time of day corresponding to optimal arousal (Ingram et al., 1982; Yoon et al., in press). The shift does not apply to everyone, but it does hold for most people. Thus, roughly 75 percent of older adults find morning to be their peak time, while only about 35 percent of college students feel that morning is their best time (Winocur & Hasher, 2002).

The shift with increasing age to better performance during an earlier time of the day is seen in many other species besides humans. In rats, for example, older members of a population perform better on memory tasks shortly after waking for the day, while younger rats tend to show a surge in their performance later in the day (Winocur & Hasher, 2002, 2004). In addition, in humans at least, the daily rhythms may have different influences on different forms of memory. Thus, older adults seem to do better on explicit memory tasks early in the morning, while younger adults seem to do better on such tasks later in the day; older and younger adults often show the reverse patterns when engaged in implicit memory tasks. Such results suggest that these different memory systems may interact with endogenous circadian cycles in quite different ways (May et al., 2005). Moreover, older adults often use compensatory strategies with respect to time-of-day effects, shifting to the mornings those tasks that are most demanding.

Q: How does the time of day tend to interact with patterns of cognitive functioning in older and younger adults?

Overall, the range and extent of cognitive changes in the elderly are large and often dramatic, making it all the more impressive that before very advanced age (80s and older) we do not see obvious evidence of these deficits in the daily lives of the elderly (see Figure 17.11). We have seen that compensatory strategies, as well as continued building of specialized expertise and adaptive shifts in chosen activities, all work together to compensate for the effects of aging. If the raw components of reaction time, speed of processing, and working memory of novel items were all that mattered to cognitive performance, then everything would be downhill after the early 20s, and there would be little to learn from our elders in college, job internships, and medical residencies. Fortunately for those adults who are well past their 20s, other aspects of cognitive ability, many of which arise from ever more elaborate knowledge bases, allow the older generations to provide added value in their contributions to society. In addition, in some areas, the elderly may actually be prone to fewer errors in reasoning than younger people, especially in interpersonal, emotionally laden reasoning tasks, where the elderly may show more effective emotion regulation than adolescents and young adults.

One major principle concerning aging is that there are enormous individual differences ranging from successful aging, in which a person retains and even improves in some abilities up until the very last months of life, to pathological aging, in which people experience a dramatic decline starting in their late 50s or early 60s (Schaie, 2008). While we have seen that some of these differences are due to genetic predispositions and to the effects of specific diseases, such as Alzheimer's disease and Parkinson's disease, it is also reassuring that for virtually all of us, healthy or ill, exercise and diet can make a substantial difference in the rate of decline of our abilities.

FIGURE 17.11 Cognitive activities and aging. Many elderly people engage in challenging mental activities, such as playing bridge, out of the conviction that one of the best ways to hold off the decline of cognitive skills is by continuing to vigorously exercise their cognitive faculties. Such activities can indeed help to slow or even halt decline, especially in tasks that are closely related to the original activity.

Changes in Personality in the Lifespan: Individual and Group Changes

We have now considered extensive evidence for patterns of change in cognitive functioning from adolescence on into old age. Many of those changes are declines in function, but some are actually improvements in function. Moreover, most of the changes are in skills or bodies of knowledge; there is far less evidence for stage-like changes in the manner of thought. As we saw in Chapters 10 and 11, stage theories of cognitive development in children have undergone serious challenges, and there is even less evidence for such changes in adults. Beyond cognition, however, there are many aspects of personality that need to be considered. These questions can be addressed in two ways. First, we can ask if personality traits remain relatively stable over time. Personality traits are typically thought of as "relatively enduring patterns of thought, feelings, and behaviors that distinguish one person from another" (Roberts & Mroczek, 2008), but such a definition raises the question of whether some traits are more likely to change over time than others. The adage "You can't teach an old dog new tricks" is very often meant to apply to personality. Therefore, it might seem that happy teenagers will be happy seniors, shy teenagers will be shy seniors, and messy children will be messy seniors (see Figure 17.12). Moreover, the strong genetic components for many personality behaviors described in Chapter 7 would seem to support that claim as well. Second, we can ask if an age group as a whole can show a change in personality style that goes beyond individual personality differences within the peer group. For example, do the elderly as a whole become more conservative, more anxious, and more depressed? Both questions have received considerable attention in recent years.

Changes in Individuals

How likely is it that a shy, anxious, and messy teenager will become an outgoing, carefree neat freak as an elderly person? For the most part, such an outcome is unlikely, especially if that person's personality is evaluated relative to his peers. If John was much shier than most teenagers, he is also probably much shier than most of his peers in the retirement home. William James, the great psychologist/philosopher of the late nineteenth and early twentieth century, was convinced that little changed after the college years:

> Already at the age of twenty-five you see the professional mannerism settling down on the young commercial traveller, on the young doctor, on the young minister, on the young counsellor-at-law. You see the little lines of cleavage running through the character, the tricks of thought, the prejudices, the ways of the "shop," in a word, from which the man can by-and-by no more escape than his coat-sleeve can suddenly fall into a new set of folds. On the whole, it is best he should not escape. It is well for the world that in most of us, by the age of thirty, the character has set like plaster, and will never soften again. (James, 1890/1950, p.121)

Continuity in personality type has often been assessed by repeated administration of personality assessment tools over a person's lifespan. One widely cited series of studies conducted in Baltimore, Maryland, argued that few personality traits change at all over much of the lifespan (Costa & McCrea, 1994; McCrea & Costa, 1984, 1994). Not surprisingly, continuity seems particularly strong for those aspects of personality that have been shown to have the strongest genetic components: extroversion, neuroticism, openness to experience, agreeableness, and conscientiousness. Known as the **Big Five** (Goldberg, 1992), these traits repeatedly emerge in a statistical technique known as **factor analysis**, which looks for relatively independent clusters of traits. One developmental version of the continuity view

FIGURE 17.12 Constancy of personality traits. Bill Clinton, shown here at ages 25 and 66, today is notably extroverted compared with his peers. But his outgoing nature was also evident in his 20s compared with his peers.

argues that personality traits arise from primarily biological causes (such as genetic factors) and that personalities evolve and develop in childhood and young adulthood but then become fixed at around age 30, as William James believed (Costa & MacCrae, 1994). More thorough longitudinal and cross-sectional analyses of personality change after age 30, however, suggest that there is continued change into old age, change that is influenced by the environments in which each person spends his life. Contextual perspectives emphasize the influences of social environments, life events, and social roles on personality, with people tending to score higher on conscientiousness when they enter the workforce and higher on agreeableness when they become parents, but lower on openness to new experiences during middle and old age (Roberts & Mroczek, 2008; Srivastava et al., 2003). Thus, the idea that people become rigidly set in personality by around age 30 does not seem to hold up. Rather, there is considerable plasticity throughout adult development (Baltes, 1997). Nonetheless, people tend to occupy the same relationships relative to their peers in terms of how they as individuals score on the Big Five traits—for example, those who are anxious when they are adolescents continue to be more anxious than their easygoing peers throughout life.

Some scholars have suggested that consistency measures have tended to focus on continuity from early life into early middle age and that later in life, as many people move into their 50s, continuity of traits starts to erode for some individuals (Lachman, 2004; Roberts & DelVecchio, 2000). As people start to assess their lives as a whole and often become more self-reflective about their roles, that increased level of introspection may cause some real reorganizations of personality. Even with this caveat, and even taking into account continued plasticity, continuity is probably the dominant pattern for major aspects of personality, especially when an individual's personality is considered in comparison with her peers. The shiest person in a large group at age 30 is likely to still be a very shy person in the same group at age 80.

There is some evidence that there may be more potential for change in individuals who suffer from personality disorders, which are manifestations of psychopathology in personality traits, than for personality change in their peers who do not manifest such psychopathologies (Clark, 2009). Personality disorders can range from paranoia to narcissism to obsessive-compulsive disorder. It now appears that, in cases of severe personality disorder, more change is possible over time. A person who exhibits extreme paranoia may show a much more muted form several years later. The reasons for this greater variability relative to his peers are not yet clear, but one factor may be that, as a person learns to change other aspects of his life to cope with a severe disorder, the disorder itself may become less prominent.

Q: Describe some of the arguments for and against the idea of continuity of an individual's personality over the course of the lifespan.

Stressful Life Events

One possible exception to the stability of personality traits over adulthood may occur in the face of repeated stressful life events. Such events appear to increase the incidence of depression in some at-risk people. Researchers have found several different patterns linking stressful life events and depression in midlife and later years (Kendler et al., 1999; Mazure & Maciejewski, 2003a, 2003b; Monroe, 2008). One pattern involves gender differences and indicates that women seem to be quite a bit more likely than men to become depressed as a result of exposure to stress (Husky et al., 2009; Kendler et al., 2001; Maciejewski et al., 2001; Sandanger et al., 2004; Stegenga et al., 2012). While it is difficult to match stress precisely for men and women (typical stressful events include relationship terminations and work-related stresses such as job loss), there consistently seems to be a pattern in which roughly equivalent stressful events are more likely to influence the lives of women than men, even quite late in life. Some analyses of twin data do suggest that researchers may overrate the influence of stressful life events on depression in middle age and underrate genetic predispositions that are independent of those events (Kendler et al., 1999), but there do seem to be residual effects arising from the stressful events themselves.

It has often been thought that the elderly are less likely to be fazed by life's ups and downs, having learned over the course of their lives that such variations are inevitable and simply must be taken in stride. There does seem to be some truth to this view, as elderly adults overall do not seem to be as susceptible as younger adults to the effects of stressful life events in terms of depression. At the same time, however, there are subgroups of elderly adults who show certain cognitive styles that can make them much more vulnerable to stressful events, with the odds of depression being from 6 to 11 times more likely in people with such cognitive styles and personality types when they encounter stressful events of specific types (Mazure et al., 2002). Thus, people who experience negative interpersonal events (for example, divorce) are much more likely to be influenced by those events if they show a high need for approval and reassurance in interpersonal relationships. In contrast, people who experience negative events pertaining to achievement (for example, being passed over for an important promotion) are influenced by those events to the extent that they put a heavy emphasis on individual success and on control. In this way, we see that while many elderly adults may have developed adaptive ways of coping with stressors, substantial subsets of elderly adults have cognitive styles that continue to make them quite susceptible. It may also be that there is a connection between cognitive styles and whether stressful events lead to depression in men and women, with more women having cognitive interpersonal styles that make them prone to depression (Mazure & Maciejewski, 2003b).

Group Changes

Above and beyond the question of whether individuals have roughly the same personality relative to their peers over the course of adult life, one can ask if people in an entire age group tend to show certain gradual shifts in personality. One way this might happen is through "cohort effects," where all people who grow up during a certain historical period, such as the Great Depression of the 1920s, have personality shifts as a cohort—for example, the ability to thrive in the face of adversity (Schaie, 1984). Moreover, there may be other ways that people in different age groups show different personality tendencies. In earlier parts of the life cycle, such patterns are largely taken for granted. Young adults and older adolescents are considered much more likely to engage in risky behaviors that may well increase their chances of being seriously injured or seriously injuring others (Steinberg, 2008; see Figure 17.13). There seems to be considerable truth to this stereotype, especially for young adult males. Automobile insurance rates are higher for young adults not only because these individuals are less experienced drivers; young people also take more risks when driving. They are more likely to engage in risky sex, unsafe travel, and dangerous patterns of drug and alcohol use both because of increased sensation-seeking behaviors and because of different perceptions of risk (Cohn et al., 1995; Greene et al., 2000; Lightfoot, 1997). In addition, when put into highly stressful situations, older adults tend to slow down and take fewer risks, while younger adults show no such decline (Mather et al., 2009). Such risky behavior by younger adults has been argued to be an important part of demonstrating their fitness in mate competition (Wilson & Daly, 1993), but it is also a bit paradoxical. Why, with most of their lives ahead of them, do young adults put themselves at such risk? Why don't the elderly members of a society, who have relatively short futures ahead of them, choose to take larger risks? As discussed in Chapter 2, the increased risk taking in adolescence may reflect relatively late emergence of frontal lobe circuit feedback on the limbic system, but it is not clear whether brain changes underlie behavioral changes in older adults.

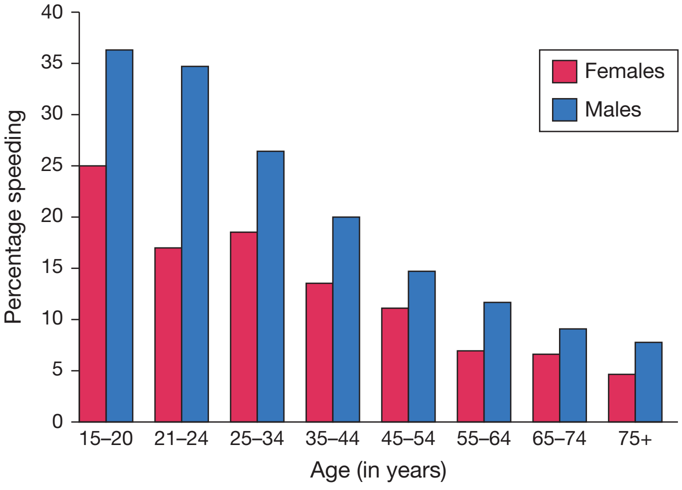

FIGURE 17.13 Speeding in fatal crashes in different age groups. Data on traffic fatalities and age are complex, as elderly people die much more often in car crashes because of their greater frailty. But if car crashes are looked at from a perspective of risk-tasking behavior, as defined by speeding, it is clear that younger drivers are much more prone to die in car accidents because they were engaging in riskier driving—that is, speeding. Adapted from Nell (2002).

Young adulthood is not the only period in which a group is thought to shift along a personality dimension such as risk taking. There have been many stereotypes about the personalities of the elderly. Are older people more anxious, more conservative, or more irritable than people in younger age groups? Despite negative views about older people, such as the stereotype of "grumpy old men," the best-documented age group changes are generally more favorable (Charles & Carstensen, 2010). For example, one well-studied dimension of personality is that of the **positivity bias** (Carstensen & Charles, 1998; see Figure 17.14). It appears that as adults grow older, they tend to have a more positive view of reality and of their experiences. This positivity bias has been demonstrated in many ways. Compared with younger people, older adults tend to pay less attention to negative events in a variety of experimental settings. In one study, participants were asked to look at side-by-side pairs of faces that depicted neutral and either positive or negative emotions. When the emotion was positive, both young and old adults were more likely to have encoded the positive face, but when the emotion was negative, the people in the two age groups showed sharply contrasting patterns. Younger adults encoded the negative face, while older adults focused their attention on the neutral face (Mather & Carstensen, 2003; see Scientific Method box). This positivity bias has repeatedly been found when older adults engage in perceptual and attentional tasks (Lee & Knight, 2009; Mather & Carstensen, 2005; Samanez-Larkin & Carstensen, 2011).

Older adults also do not remember negative information as well as they remember positive information. One study with 300 nuns looked at their memory of responses on a questionnaire that they had filled out 14 years earlier

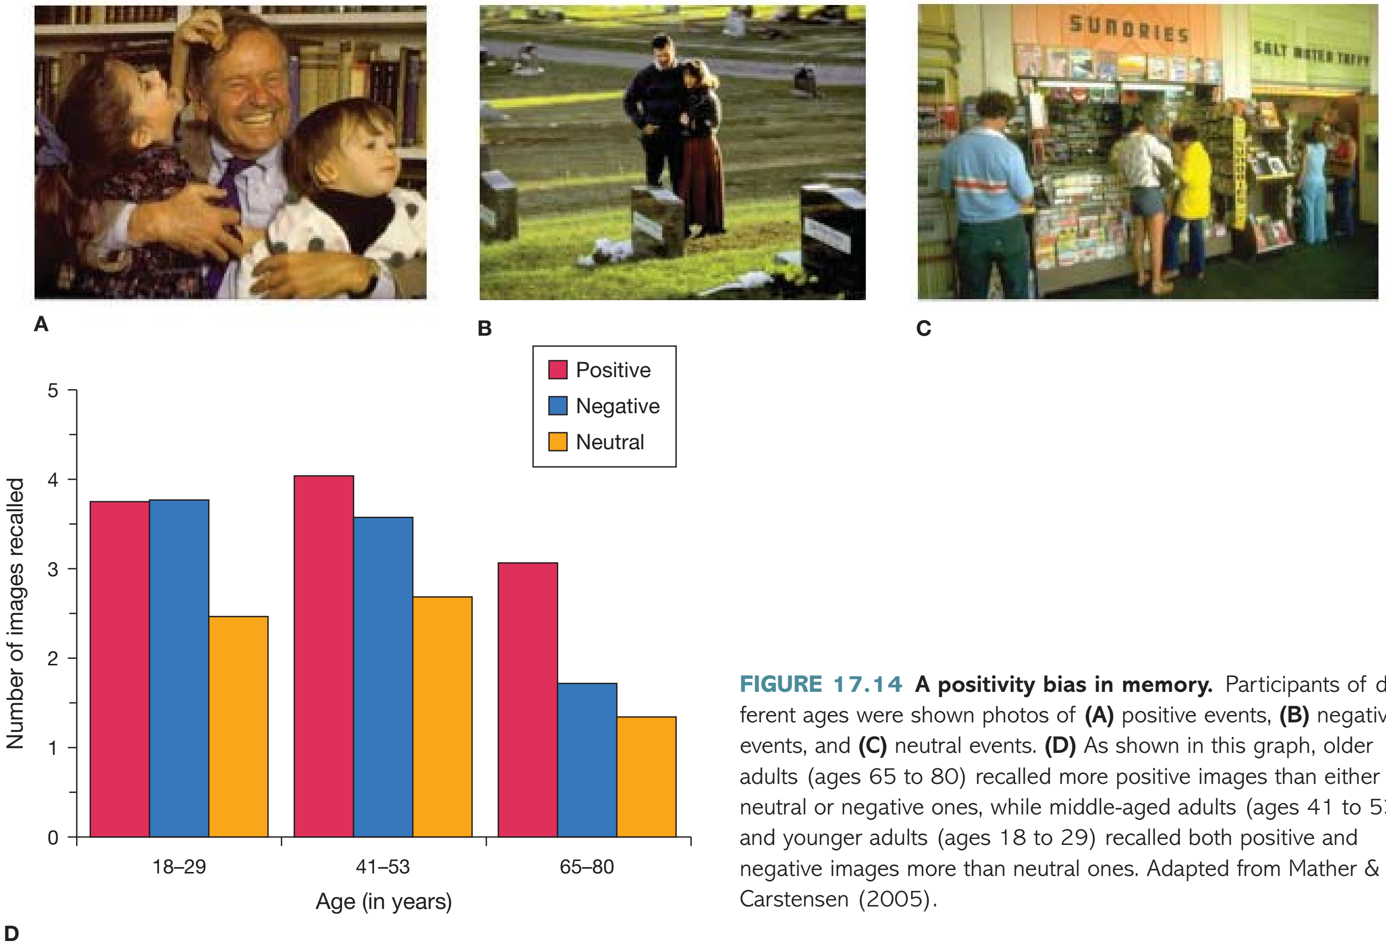

FIGURE 17.14 A positivity bias in memory. Participants of different ages were shown photos of **(A)** positive events, **(B)** negative events, and **(C)** neutral events. **(D)** As shown in this graph, older adults (ages 65 to 80) recalled more positive images than either neutral or negative ones, while middle-aged adults (ages 41 to 53) and younger adults (ages 18 to 29) recalled both positive and negative images more than neutral ones. Adapted from Mather & Carstensen (2005).

(Kennedy et al., 2004). The nuns ranged in age from 47 to 102 years at the time of recall. Older nuns showed a strong bias toward recalling items in their questionnaires more positively than they had originally reported them 14 years earlier. Older nuns were seen as more motivated to provide a positive interpretation of past life events, perhaps as a way of regarding their lives, as they neared their ends, as more worthwhile. (Since more than 60 percent of the nuns who had originally filled out the questionnaire had died during this period, the impending end of life was likely to be very salient to the older nuns.) Over shorter time intervals, older people also show a distinctly better memory of positive pictures compared with negative and neutral ones (see Figure 17.14).

Positivity effects also have an influence on decision making. For example, when college students and people in their 60s were asked to list positive and negative features of several common objects (for example, a pen, a mug), those in the older group tended to list more positive features and fewer negative ones. Both groups then got to pick an object to keep, and those in the older group declared more satisfaction with their choice both immediately and after 2 weeks (Kim et al., 2008). This difference in satisfaction occurred only when both groups were asked to evaluate each object and list positive and negative features. If they were simply asked to pick an object and then rate satisfaction with their choice, there was no difference between the groups. Thus, the positivity bias influences feature choice in the evaluation task, which then influences satisfaction with the choice. There may be real-world implications concerning strategies used to influence decision making in older adults as opposed to younger adults. Having older adults generate a list of pros and cons for a decision is more likely to result in their being satisfied with the decision than it is for younger adults.

At the neural level, this positivity effect has been demonstrated by showing that the amygdala, a brain region heavily involved in emotions, shows markedly less activation in response to negative stimuli than to positive stimuli in older adults, while showing strong responses to both kinds of stimuli in younger adults (Mather et al., 2004). Because negative events do not elicit as strong an emotional response in older adults, they are not nearly as motivated to attend to or remember negative information. It appears that older adults also focus more on emotional regulation and are often better at it than younger adults, being less quick to feel anger in reaction to negative events, reacting less strongly, and letting anger and negative affect

SCIENTIFIC METHOD: The Positivity Bias in Older Adults

Hypothesis:

Older adults are biased to attend more strongly to positively slanted forms of information.

Method:

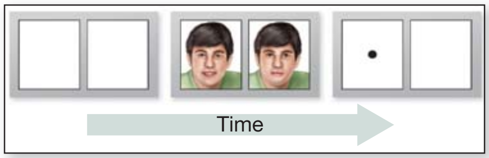
1. Fifty-two younger adults (18 to 35 years old) and 52 older adults (62 to 94 years old) participated.
2. All participants started by looking at a blank screen across the room.
3. Two faces appeared for 1 second: one with a positive or negative emotion and one that had a neutral expression.
4. A small dot then appeared where one of the faces had been, and participants were asked to say what the emotional expression had been on that face.
5. The researchers measured the speed of the participants' response.

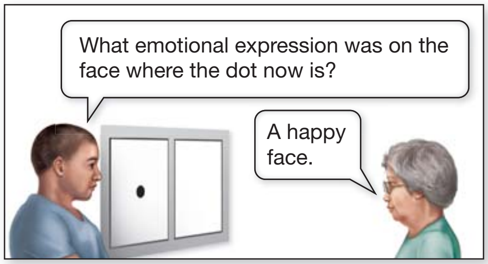
Results:

Positive scores indicated faster responses when the dot appeared after an emotional face than after a neutral face. Negative scores indicated slower responses when the dot appeared after an emotional face than after a neutral face. Younger adults had faster responses for both positive and negative faces than they did for neutral faces. Older adults were much faster in responding to positive faces but slower in responding to negative faces.

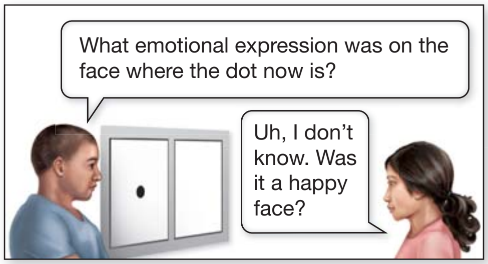
Conclusion:

Older adults track information about positive faces more effectively, showing a positivity bias for information.

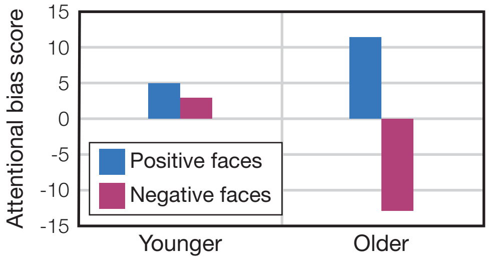




What emotional expression was on the face where the dot now is?
A happy face.



What emotional expression was on the face where the dot now is?
Uh, I don't know. Was it a happy face?



Source study: Mather & Carstensen (2003).

dissipate more quickly. One reason for this shift in focus is the related finding that, as people approach the end of life (including younger people with terminal illnesses), they tend to shift their priorities more to goals related to emotional well-being in the present and less to those related to gaining knowledge for future use (Mather & Carstensen, 2005). Older adults also show an asymmetry in neural processing of anticipated gains and losses compared with younger adults. This, too, may be related to the positivity bias. In particular, when anticipating rewards, individuals from both age groups show equally strong neural responses in reward-related centers. But when they are anticipating losses, older adults show considerably lower levels of activity in both the dorsal striatum and the anterior insula, which are regions related to processing gains and losses (Samenez-Larkin et al., 2007). This pattern may result in older adults having less anxiety associated with worries about potential future losses, which may thereby lead them to be more optimistic and to show the positivity bias (Samenez-Larkin & Knutson, 2014).

Beyond the preference for noticing and remembering positively construed information, there are other ways in which personality for an entire age group tends to change as people age. Again, while a person may still be disagreeable relative to his same-age peers, he may become much more agreeable in more absolute terms (comparing across all ages) as he grows older. As seen in Figure 17.15, these changes can be very substantial in some areas, such as conscientiousness or agreeableness. Overall, scholars have repeatedly noted that these changes tend to be ones that impartial observers would rate as desirable. Thus, as people grow older, their personalities tend to shift in ways that others would see as making them better people (Roberts & Mroczek, 2008).

Sometimes, apparent age-related shifts in personality may simply reflect changing realities. Older individuals are

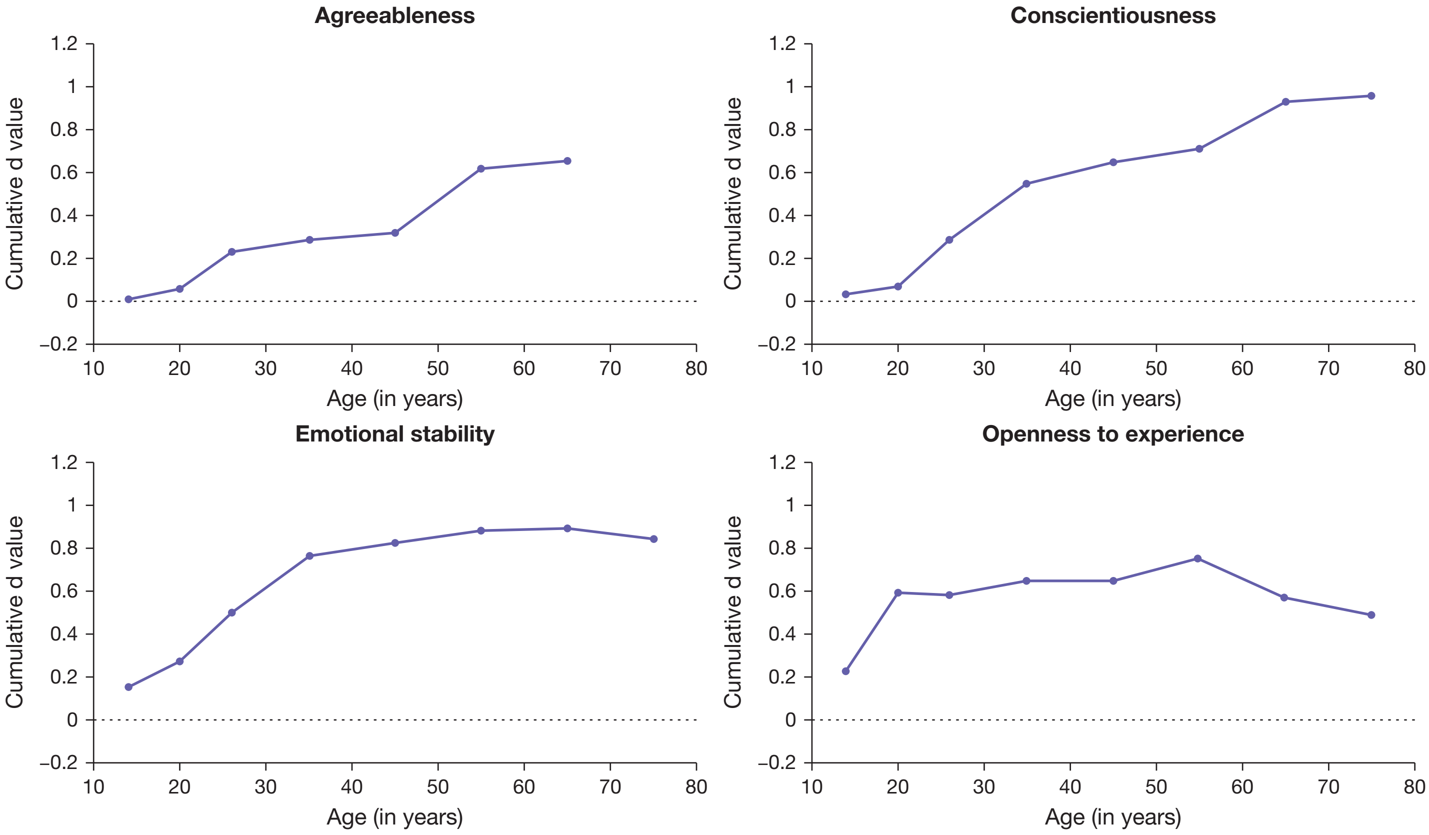


FIGURE 17.15 **Group changes in personality.** While people tend to show consistency in personality types relative to their same-age peers, age groups as a whole can show quite dramatic changes with increasing age along various personality dimensions. Here we see substantial rises in three dimensions (agreeableness, conscientiousness, and emotional stability) and relative stability in another (openness to experience). From Roberts & Mroczek (2008).

often described as being more anxious, but the increase in anxiety may not be as much an endogenous change in personality as a reflection of the greater likelihood of injury in their lives. People in their 90s, for example, are highly likely to suffer a broken hip from a fall. Their greater anxiety about falling when getting around may simply be a rational appraisal of the ways in which they are more physically at risk, just as younger adults with at-risk conditions, such as asthma or heart problems, might be more anxious.

More broadly, age group effects raise questions about whether there are general life stages that people tend to pass through, stages that might be related to some trends in personality change in different age groups.

Q: What are some ways that older adults as a group tend to shift in terms of their personality characteristics, their views of reality, and their remembered experiences?

Stages of Life?

As seen in Chapters 5 and 10, the notion of stages of cognitive development in infancy and childhood were problematic. It might still be the case, however, that within the broader context of the full lifespan, there are stages of development. For the most part, proposals of such stages have not been about cognitive functioning per se and have been more about social, emotional, and general life perspectives. As mentioned earlier in Chapters 7 and 13, the best-known theory of lifespan stages was put forth by Erik Erikson (see Figure 17.16).

Erik Erikson's Approach

Erikson was initially trained in the psychoanalytic tradition and in fact studied under Anna Freud. At the same time, he had a strong background in anthropology, which led him to take into account the effects of culture to a far greater

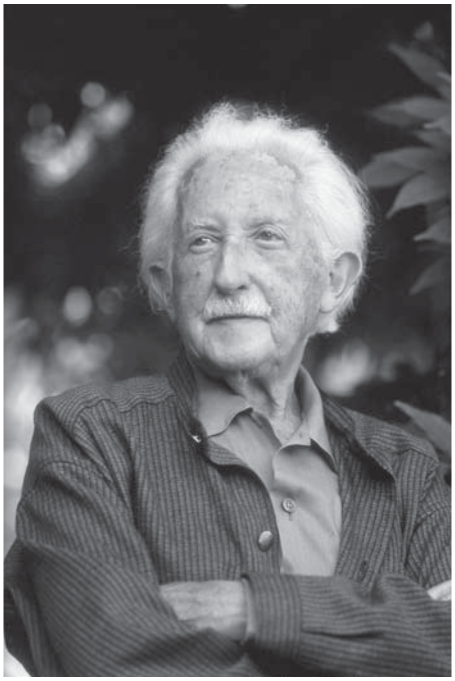

FIGURE 17.16 **Erik Erikson.** Erikson proposed a series of stages of psychosocial development that applies to the entire human lifespan and is marked by a distinctive conflict at each stage that an individual either masters positively or endures negatively.

extent than either Freud or his daughter. Erikson proposed eight stages of psychosocial development, as summarized in Table 17.1, with each stage organized around a type of **psychosocial conflict** (Erikson, 1950). These conflicts are the challenges people face in relating to others or to society at large. They occur throughout the lifespan and must be addressed in order to establish an identity within the social world. The challenge at each stage may be successfully handled and form a good foundation for the next stage, or it may be unsuccessfully managed and not only form a weak foundation for the next stage but also reappear later, especially in times of stress. Let's consider each stage in more detail.

Stage 1: Trust versus Mistrust As babies start out in life, relationships with the mother are thought to be central. If the mother or other primary caregiver is able to respond to the baby's needs and make him feel safe and secure, the infant is likely to develop a sense of trust in those around him. By contrast, if the mother is unable to meet his needs, the baby is likely to become mistrustful and suspicious of others.

Stage 2: Autonomy versus Shame/Doubt As children start to walk about and explore their environments, their parents need to grant them some sense of autonomy while also making sure that they do not get into too much trouble. Ideally, parents will allow their children to explore and move about in the freest manner that still ensures their safety. But Erikson believed that if the parents are too controlling or too protective, their children will develop doubts about their own abilities and shame at their incompetence.

Stage 3: Initiative versus Guilt Preschool children develop a better and better sense of their own personal responsibility. As their circle of relationships extends to the family as a whole, they become more aware of how their actions influence others. They need to learn to take the initiative as they seek to gain mastery of a wide variety of life tasks, but too much initiative without any guilt may lead to psychopathic behavior, producing a child without

Stage	Approximate Age (in years)	Developmental Period	Psychosocial Conflict	Most Important Relations
1	0–1.5	Infancy	Trust vs. mistrust	Mother/primary caregiver
2	1.5–3	Toddler	Autonomy vs. shame/doubt	Parents
3	3–6	Preschool	Initiative vs. guilt	Family
4	6–12	Childhood	Industry vs. inferiority	Neighborhood/school
5	12–18	Adolescence	Identity vs. role confusion	Peer groups
6	18–30	Young adulthood	Intimacy vs. isolation	Partners, friends
7	30–50	Middle age	Generativity vs. stagnation	Family, coworkers
8	50 and older	Later adulthood	Integrity vs. despair	Mankind /"my kind"

TABLE 17.1 **Erikson's stages of psychosocial development.** Erikson proposed eight stages of psychosocial development, each marked by a distinctive form of conflict that an individual has to address to help construct his social identity.

DEVELOPMENT AND SOCIAL POLICY

When Is It Acceptable to Deprive the Elderly of Some Rights?

At first, it might seem outrageous to discuss depriving the elderly of certain rights, but in fact it happens every day with the implicit consent of most members of the larger society. Unfortunately, many people start to have diminished psychological capacities toward the end of their lives. Certainly not everyone, but a large number of people in their 80s and 90s show serious patterns of mental decline. At some point, that drop in abilities has strong social policy implications.

An often-discussed example concerns wills. At what point does a person who is in intellectual decline lose the right to change her own will? Offspring often contest changes in wills that deprive them of resources on the grounds that the changes were made by a parent who was no longer "all there." When wealthy Aunt Hattie changes her will so as to give all her earthly goods to her butler, her heirs may claim that she was no longer able to think clearly. What counts as sufficient grounds for depriving her of the right to change her own will? One well-known case concerned the hotel owner Leona Helmsley, who left $12 million to her Maltese dog "Trouble" and nothing to two of her grandchildren. The grandchildren argued that Helmsley was mentally incompetent when she signed that version of the will, and a judge agreed, cutting back Trouble's inheritance to a mere $2 million and giving some of the remainder to the grandchildren (Roberts, 2009).

Legal scholars continuously wrestle with appropriate guidelines (Frolik & Kaplan, 1999; Schuster, 1998; Walsh et al., 1994). But wills are only the tip of an ever-growing iceberg as more and more people reach advanced age. When should we deprive the elderly of the right to drive? We know that past age 65 or so, there is an increased risk of accidents. How much of an increase is too much? Many states recognize this problem by requiring that the elderly have far more frequent renewals of their driver's license and that they show up in person rather than renew by mail (Grabowski & Morrisey, 2001; McLachlan, 1997).

What about the right to vote? That nearly sacred right has not been challenged as much for the elderly, but there is no logical reason not to challenge the right to vote of a person of severely diminished capacity. Consider the case of a man with advanced senile dementia whose wife helped him vote in the 2000 Florida election. The man thought it was 1942 and that Franklin Delano Roosevelt was president. His wife went into the voting booth with her husband and cast the ballot for her husband (voting for George Bush in an election where a few hundred votes decided the U.S. presidency; see Vedantam, 2004). Increasingly, there has been an interest in the legal basis for allowing elderly people with severely diminished capacity to vote, especially since some of the most pivotal "swing states" in elections have large numbers of elderly voters. In Florida, nearly 500,000 people had Alzheimer's disease in 2000 and a sizable number

a conscience. Too much guilt, however, leads to excessive inhibition in the child and trepidation about her own actions. This illustrates a point that Erikson believed was true of the conflicts in all of the stages. While one of the contrasting traits is usually heavily favored, a healthy individual has some degree of both traits. Without any initiative at all, a child might not be likely to try any new behaviors or social situations. Without guilt, a child might be too impulsive, trying new behaviors without regard to how they affect other people.

Stage 4: Industry versus Inferiority An elementary school child is confronted with tasks in which high levels of achievement are valued. As relationships in the neighborhood and school increase in importance, children become aware of how their performance compares with that of others. The school and neighborhood value high levels of achievement and reward industry. If goals and tasks set up by their communities are appropriate, children develop a sense of competence as they accomplish a task. A feeling of industry emerges. Alternatively, if the school and community ask too much of a child or do not give the child a fair chance, the child may develop a sense of inferiority and may see herself as a failure.

Stage 5: Identity versus Role Confusion Adolescents are seen as striving to find their place in the world. If they succeed, they develop a sense of their role in life and feel that they have a future path that will lead them into adulthood.

of them voted, raising the possibility that the president of the United States won his election on the votes of some individuals whose capacities were well below that of an average 12-year-old. Indeed, in many prior elections, as many as 70 percent of the people in a population who had severe dementia nonetheless voted (Henderson & Drachman, 2002; Vedantam, 2004). Moreover, voting rates are highest among people in the 65- to 74-year-old age group (Karlawish et al., 2004).

Some legal scholars contrast driving, which they call a "privilege," with voting, which they call a "right." But even with that difference, it is not clear that everyone past age 18 should be voting regardless of their mental status. After all, "moral status" prevents many felons from voting. Some state laws on voting do set restrictions based on criminal records and mental incapacity, but any limits on voting rights, especially of the sort that gradually increase with aging, are intensely controversial. One recent appeals court outlined the following principle: "A person has the capacity to vote if he or she understands the nature and effect of voting and has the capacity to choose among the candidates and questions on the ballot" (Karlawish et al., 2004). Yet, for that principle to be implemented, there needs to be a standardized and fair way of assessing cognitive understanding of the "nature and effect of voting" and "the capacity to choose."

Regardless of the details of this debate and how it turns out, one fact is likely to dominate. There is immense variation in patterns of decline among the elderly, and it would be impossible to set up any restrictions of rights solely on the basis of chronological age. For example, a 95-year-old might be vastly more intellectually intact than a 75-year-old. While it might be best to keep some elderly people from driving, others might actually be more careful drivers (see Figure 17.17) and still deserve to have the right to drive. Clearly, we need better ways of assessing patterns of decline for each individual in his own right. Moreover, a particular person's pattern of decline may be relevant for restricting just one narrow range of rights, such as driving, and not any others. It seems likely that psychologists, the people most qualified to make such assessments, will be very active participants in determining when it is appropriate to reduce the rights of the elderly (Baker et al., 1998; Ball et al., 1993, 2006). One likely outcome is that quite different profiles of psychological capacity will be considered adequate for different sorts of legal procedures and public rights, requiring particular tests for each sphere of life potentially affected by aging.

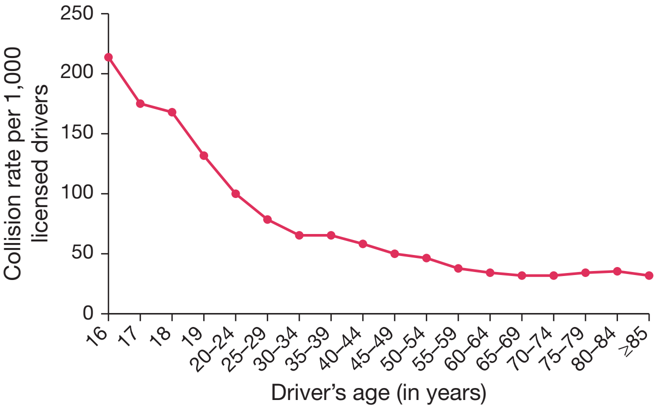

FIGURE 17.17 **Collision rates by age.** Older drivers, even very old ones, are not nearly as likely to get into an accident as younger drivers. Part of the reason lies in the fewer miles driven by the elderly. But even taking into account those fewer miles driven, people older than 85 years still have a lower accident rate than people in their early 20s.

If they fail, they may reject the society at large and the roles that it offers. They may lack a sense of group identity or identify with a group that defines itself as rebellious and that is against any traditional life roles.

Stage 6: Intimacy vs. Isolation In this stage of life, a critical task is that of forming close interpersonal bonds, typically those of a married couple. Intimacy may be a major challenge for many young adults, not just because of the difficulties of forming stable close bonds, but also because of the dangers of excess intimacy in the form of promiscuity. At the other end of the extreme, failure to develop intimacy may result in a sense of isolation, leading to feelings of loneliness and perhaps bitterness toward those who do have intimacy.

Stage 7: Generativity versus Stagnation Generativity consists of making contributions to the world and to the next generation. As people go through middle age, generativity may take the form of having children and raising them. Or it could take the form of making major contributions in a career, contributions that enhance the lives of others and that do not just advance the self. Society as a whole benefits from the activities of a generative person. A person who shows stagnation, however, tends to be overly concerned with her own selfish needs, making no contributions to the community at large.

Stage 8: Integrity versus Despair The final stage is a potential capstone on a life of positive prior stages or the final act in a tragedy of a life gone wrong. People who achieve integrity feel good about the life they have led, mistakes and all. They see themselves as having made contributions of value, having taken a good journey, and they are content with their gradual exit from the main stage, feeling they have done their part. Others are consumed by an enveloping sense of despair as their life starts to end, and they feel that they have not accomplished what they had hoped to in their life. They see the present negatively and the future even more bleakly. Every sign of further aging makes them feel more impotent and of less consequence. (Fortunately, the positivity bias may shield some adults from despair even when their lives have had some serious failings.)

Q: What are the psychosocial conflicts that organize each of the eight stages of Erikson's theory of lifespan development?

Understanding Stages of Adult Development

Although the stages described by Erikson have not been subjected to careful experimental validation, there is a broad consensus that many people do go through life transitions roughly like those that he describes. Moreover, his stages have global similarities to those proposed by other theorists of adult life stages (Levinson, 1986; Schaie, 1994, 2008). A critical question, however, is whether the stages are manifestations of a gradually unfolding process inside the self or whether they are almost inevitable consequences of the different roles that society and culture imposes on individuals. With his strong background in anthropology, Erikson was deeply sensitive to the influences of culture, but his stages have often been described as more intrinsic developmental changes occurring in the individual.

Consider for a moment how some stages are dictated by the surrounding culture, especially Stages 6, 7, and 8. In Stage 6, most people form a stable long-term relationship with a single significant other, a process that requires mastering the challenges of intimacy (or coping with the consequences of isolation). Moreover, as most cultures favor monogamous relationships, the surrounding culture pressures individuals to form long-term pairings. Stage 7 is more or less a consequence of Stage 6. People who have children and remain invested in them will do whatever they can to promote their well-being and advance their futures. And most people who do not have children will feel compelled to contribute in either material or social ways to society at large. Finally, Stage 8 reflects some of the inevitable decline in abilities toward the end of life. Moreover, as people enter their later years, they reflect on the sort of life they have lived and whether and how they have contributed to society. It is also quite easy to frame these last few stages in terms of evolutionary psychology, emphasizing the need to find mates, care for offspring, and then disengage so that the next generation can take over.

It is interesting how often some fundamental contrasts of personality seem to be repeated at various stages. For example, we have repeatedly seen how impulsive versus inhibited aspects of temperament describe younger children. Similarly, some of the tension that occurs in each stage consists of striking a balance between openness to new experiences versus being closed off from trying new things. A second dimension, concerning optimism versus pessimism, seems to be an important part of the conflicts and outcomes that occur in the later life stages. Thus, a few contrasts along personality dimensions that tend to remain stable over development, along with some nearly inevitable transitions imposed by the culture at large, may be helpful in understanding both the general Eriksonian stages as well as the conflicts that occur at each stage and how the challenges from one stage carry forth to the next—that is, how they show continuity in an underlying personality trait.

There is also a delicate balance between dwelling on the crises in life and trying to ignore them altogether. Being haunted by regrets about all the things we should have done but did not can lead to a depressive view of life as a failed existence. Alternatively, never looking back and evaluating our history and denying the mistakes in our past can also be detrimental to personal growth. When older adults are asked to describe how past failures or other actions they regretted influenced their subsequent lives, it appears that those who took stock of the experience and used it as an opportunity to grow and change showed more personal development and more contentment with their life as a whole. Those who did so seemed to attain a "mature happiness" that often seemed to have strong components of both humility and courage (King & Hicks, 2007).

What Does It Mean to Be Old?

When we describe a person as "old," our meaning is tied to the present day and may not be the same as that used in other places or times. Consider, for example, how much lifespan has changed in recent history. In many developed countries, the average lifespan has more than doubled over the past few hundred years (see Figure 17.18). What it means to be old has changed dramatically from a time when a 60-year-old was considered to be an elder to our present time when in many cultures a person of this age is considered to be in

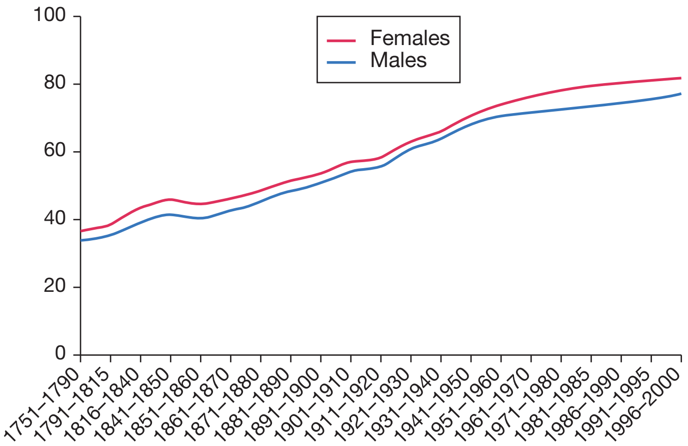

FIGURE 17.18 **Increase in average lifespan.** As seen in this graph, the average lifespan in Sweden more than doubled in 250 years.

midlife. Moreover, with the average lifespan in some developing countries less than half that in developed countries, the age at which a person is considered old in Swaziland may be considered middle-aged in Japan.

Changing views of the roles we should occupy at different ages are often evident in how visual media portray people of different ages. Whether it be the cover of a nation's leading magazine about senior citizens (see Figure 17.19) or the depictions of 50- and 60-year-old characters in film and art, the notion of "old" seems to have clearly shifted upward in age. In addition, older adults are increasingly keeping physically fit and engaging in activities that were formerly restricted to younger adults. At age 70, Mick Jagger continues to perform as a rock star to sold-out audiences in large stadiums. Former president George H. W. Bush went skydiving on his 85th birthday, and countless other men and women in their 70s and beyond are skiing, surfing, and doing many other activities that only a few years ago were thought to be the domain of adolescents and young adults. Of course, many older adults do have real limits as to what they can do, but it is very difficult to make generalizations about an entire group of older adults.

The age when people marry has also changed considerably in developed countries from a time when many college-age women were worried about graduating without a fiancé in hand to the present, when many are worried about how a marriage in their early or mid-20s might hinder their careers. When people do marry later, a cascade of other changes can also occur. People who marry later tend to have children later and hence are older when their own children go on to college and careers, get married themselves, and start their own families. In those families, it may be relatively rare for grandparents to see their grandchildren graduate from college, while such events were more common for those who married young and had children at an early age.

Average family size has declined dramatically in many developed countries, with the consequence that parents' roles outside the home are correspondingly larger. Women have entered the workforce in unprecedented numbers in many countries over the past few decades, and the role of homemaker is no longer viewed as the only way to have a productive and meaningful life. There is every reason to believe that many equally dramatic changes will happen over the next few decades as well.

One particularly interesting case of changing perceptions of age-related roles concerns the debate about whether people go through midlife crises. The notion of a midlife crisis has waxed and waned in recent years. It normally refers to a time when a person in his 40s, more often a male, goes through a period of dramatic self-questioning and reevaluation, sometimes said to be brought on by a relatively sudden awareness of an inevitable and not-too-distant future death (Jacques, 1965). In reality, however, there is little reliable evidence that men or women regularly go through such a crisis in their 40s more than in any other decade in their lives (Freund & Ritter, 2009; Lachman, 2004). There are important transition points throughout adulthood, ranging from the arrival of children, to having an empty nest, to finding that a career path has reached an apogee lower than had been expected, to dealing with retirement. Each of these, and many others, can precipitate a crisis of introspection and reevaluation, but no one decade seems to dominate

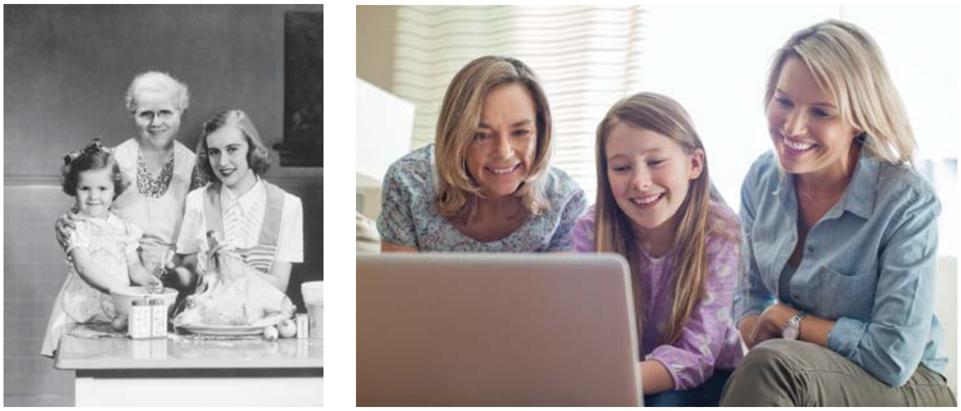

FIGURE 17.19 **When is a person old?** As seen in these photos of grandmothers with their daughters and granddaughters, views of senior citizens have changed rather dramatically, suggesting that cultural shifts in what it means to be old may have a dramatic influence on how people perceive their life roles.

in terms of having the most dramatic crisis. Taken together, all of these changes clearly relate to what it means to be old and what ages are considered to be old and what a typical progression through life would be. And all of these factors influence the stereotypes that younger people have in mind when they think about the elderly.

Q: What is the evidence for a distinct period when a person is in his 40s that is known as the "midlife crisis"?

Stereotypes and Ageism

We do not always regard the elderly in a positive light. Moreover, many negative impressions of the elderly may be inaccurate (see Figure 17.20). These inaccurate negative biases toward the elderly are often known as **ageism**, which in many ways is analogous to racism or sexism. We have already seen how the "grumpy old men" stereotype does not reflect the general tendency of the elderly to actually become more agreeable with age. There are several other ways in which we stereotype the elderly that may do them, and our culture at large, a major disservice. Perhaps the most important is a general perception of a decline in abilities. But we have clearly seen throughout this chapter that life after age 20 is not one of uniform decline. While it may well be true that some of the component building blocks of mental and physical ability show continuous decline from college onward, the more complex configurations of actual real-life abilities can stay level or even increase well into a person's 70s, whether those abilities concern decision making, expert performance in a local domain, or the ability to regulate emotions. It is therefore important not to seize on some salient aspects of decline, such as slower motor speed or reduced physical strength, and not to make overly broad inferences from such information.

FIGURE 17.20 Stereotypes of the elderly. If you find this image remarkable, it may be because it counters strongly held stereotypes about the elderly.

There is also a perception of decreasing competence in the elderly. But this perception is in most cases not justified. For example, older workers are often rated as less competent in carrying out their jobs, yet actual performance measures usually find them equal and sometimes more competent than younger workers (McCann & Giles, 2002). In addition, attributions about failure for younger and older adults are often different. When a younger adult fails on a memory task, the failure is usually attributed to lack of attention or effort, but when an older adult fails on the same task in exactly the same way, the failure is much more often attributed to declining cognitive abilities (Cuddy et al., 2005; Erber & Long, 2006; Hummert, 2011). The stereotypes about the elderly can be so strong that they can override other well-known strong stereotypes, such as those related to gender (Cuddy et al., 2005).

There may be a link between perceptions of competence and a perception of the elderly as warm. More broadly, people tend to see those who they evaluate as incompetent in a warmer light and those who they see as highly competent as more devious and cold (Fiske et al., 2007). This might be seen as softening the harshness of views of the elderly as less competent, but it can also help predators to be more confident that they can take advantage of the elderly without retaliation or repercussion. In addition, in situations in which the elderly are meant to be partners in decision making, such as in discussions with doctors about critical health care decisions, doctors may not provide as much information as they should to an elderly patient because of a mistaken stereotype about incompetence (Adelman et al., 2000). This is not to say that doctors and others who provide information to the elderly should not make simple changes to the wording and sentence structure that can hugely help some older people more easily comprehend an explanation (Liu et al., 2009). But no one should assume lower levels of cognitive competence and refrain from providing information that could help an individual—elderly or not—in making a difficult decision.

Assumptions about the elderly can change the nature of communications with an elderly person for the worse. Assumptions of incompetence in hearing and comprehension can lead others to alter their speech in ways that reduce message quality for the elderly. Speakers often fail to realize that there is enormous variation among the elderly in hearing and comprehension ability and speak to elderly people who have excellent hearing and comprehension as if they were deaf and confused (Hummert, 2007). They also fail to realize that even some adults who do have hearing and memory problems have learned ways to adjust to those limitations through such means as hearing aids and taking notes. With those adaptations, older adults may be fully capable of comprehension at a high level. There is also a general tendency, especially among younger adults, to speak in patronizing terms to the elderly—and sometimes even other elderly adults will be patronizing as well to their peers. In general, the less competent a person is perceived to be, the more patronizing the speech will be. Unfortunately, patronizing speech can make the elderly feel like they are having more communication problems (Kemper & Harden, 1999), which in turn can cause the speaker to see them in an even worse light and to then engage in even more patronizing speech. Such a pattern of interactions creates a destructive negative-feedback loop in which stereotypes can end up seeming to be confirmed because of their effects (Hummert, 2007, 2011). In addition to the influence of perceived incompetence, there seem to be residual biases in which younger adults, and even senior peers, judge communication with the elderly to be a negative experience, even if there are no obvious differences in communication quality (Giles et al., 2008). In short, a variety of stereotypes, which are often inaccurate, plague interactions with the elderly in ways that not only impair opportunities for the elderly but also deprive everyone else of the elderly's skills and talents.

Cultural Variation in Stereotypes and Ageism?

Perhaps the negative stereotypes about the elderly are limited to certain cultures. For example, ageism might be more pronounced in individualist cultures, such as the United States, than in collectivist cultures, such as Japan, because concerns for the common good in collectivist societies might result in more respect for the elderly (see Figure 17.21). This position has often been suggested, but most research suggests that it is not the case. Not only is ageism seen across a wide variety of cultures; it takes on similar forms in most cultures. Thus, across both collectivist and individualist societies, developed and developing countries, and cultures in the East and West, older people are regarded as both less competent and warmer than are younger adults (Fiske, 2012; Fiske et al., 2007). In terms of more specific cognitive capacities, people in both Western and Eastern cultures strongly stereotype older members of their cultures as having defective memories, again a global stereotype that can do a great injustice to many elderly people who show no memory problems in a wide range of tasks (Ryan et al., 2009).

FIGURE 17.21 Cross-cultural views of the elderly. It is commonly believed that many Eastern cultures revere the elderly and view them with much more positive regard than Western cultures. While this may once have been true, recent studies suggest negative views of the elderly are quite similar across cultures.

Have negative stereotypes always been present in all cultures? The evidence here is weak. Based on descriptions of the elderly in some cultures' literature and customs, it might seem that the elderly are held in such respect that negative stereotypes might not be possible. Yet, some stereotypes might remain concealed behind a more public veneration of the elderly. Some have suggested that collectivist cultures may have shifted to more negative views in the past few years because of other changes, such as the rapid acceleration of technology, which can make the elderly look less competent (Fiske et al., 2007). (Just think of the way some elders groan about the difficulties of using a cell phone.) More thorough historical analyses may reveal whether such accounts are true.

Q: What are some factors that have contributed to greatly changed views of what it means to be old?

Some have argued that relatively confining roles of what people are supposed to do at various points in their lives have started to disappear in more recent years in many Western cultures (Neugarten & Neugarten, 1986). Thus, it used to be that there were clearly age-appropriate and age-inappropriate activities throughout the lifespan. A few decades ago, people were expected to marry and have children in their 20s. Thirty years ago in Japan, a young man was expected to start working at a corporation as a "salaryman" and continue loyally working for that same corporation for the rest of his life; today job and even career changes are much more common in Japan. People past age 65 were, in earlier years, expected to retire and largely withdraw from professional activities. Yet, with the abolishment of mandatory retirement ages in some countries, such as the United States, many people continue working into their 70s. And when retirement accounts began to shrink after the great recession of 2008, it became common to see retirees leaving retirement to take on new jobs that were often quite different from their old ones.

We seem to be living in a time of considerable flux with respect to what people are supposed to do at various ages in life. Moreover, the examples we have just considered come largely from the majority cultures in developed countries. But age-related life roles can be very different in other groups. To give just one personal example, some years ago I worked briefly in a very impoverished area of Jamaica. I was stunned to learn from several local people that there was a powerful expectation that young girls get pregnant in their early teenage years. Having a child at that young age was considered a sign of maturity and coming of age. Girls in those poor communities who resisted having early pregnancies were often mercilessly taunted as "mules," implying that they were sterile and unable to have children.

We may all go through important life transitions as adults, but those transitions should be understood as highly relative to the culture we inhabit and to the particular group that we belong to in that culture. More than any other time in the lifespan, adulthood may require a careful analysis of how specific cultures frame life roles at various points in the life cycle and the extent to which those roles are relatively stable or undergoing rapid flux.

Conclusions

There are many changes in physiological and psychological functioning after young adulthood, but it is a gross oversimplification to see those changes as either patterns of continuous and universal decline or as continued development of the sort found in childhood and adolescence. Despite substantial declines in many of the basic components of cognition, such as speed of processing, memory, and attention, some forms of cognition show little or no decline in the later years. Other forms of cognition continue to improve, even in the last decade of life, and they reflect a process of continuous development of a skill, such as doing crossword puzzles and regulating one's emotions during decision making. These patterns of change are better understood by recognizing that, just as children are active participants in the changes that occur early in the lifespan, older adults are active participants in the changes that occur later in the lifespan. Processes such as optimization, selection, and compensation all help aging adults refine some cognitive skills in ways that help them to maintain or continue to improve these skills. At the same time, people do tend to show continuity of personality traits as they grow older. Thus, changes produced by compensation must be understood as occurring within personalities that are likely to stay relatively the same with respect to their peers. Changes that occur in the later years are also likely to be quite different in the decades to come as people live longer and stay healthier in their later years.

We have also seen that the entire developmental progression through the lifespan is continuously changing as a function of medical advances, emerging attitudes, new ways of viewing exercise and diet, and shifting roles in the culture at large. Compared with the other periods of development, adulthood is especially likely to look different in the decades to come. It may become routine for children born today to live past 100 because of medical advances and lifestyle changes. Such increased longevity will have massive consequences, influencing when people retire, how they support themselves in retirement, how they relate to their children and grandchildren, and how younger adults adjust their lives in light of such an extended future. In addition, a new wave of medical issues may arise as some parts of the body stay healthy much longer than others. To cite one example, osteoporosis, especially in women, may be especially hard to slow down, and even if centenarians are otherwise very healthy, many may be extremely fragile in the face of even the slightest fall. As these and other changes occur, the nature of ageism and stereotypes about the elderly will surely change as well, not necessarily becoming less unfair, but definitely different from what they are today.

STUDY AND REVIEW

SUMMARY

Physical and Physiological Changes in Adulthood

- Any account of the physical and physiological changes that occur in adulthood must address the ways in which those processes are changing over the course of history in light of medical advances, lifestyle changes, and new cultural practices. The distinction between successful aging and pathological aging illustrates many ways in which older individuals can thrive far longer in life than was considered feasible even a few decades ago, while others may suffer from irreversible debilitating diseases.
- Pathological aging may also involve several diseases that occur more frequently, but certainly not inevitably in the elderly. These include Parkinson's disease, Alzheimer's disease, and other forms of dementia that can rise quite dramatically in incidence as some people progress through their 80s and 90s.
- People can age at different rates and any account of changes in adults must recognize the considerable variances that can occur and how they are related to successful and pathological aging. Chronological age and biological age are increasingly distinct concepts.
- Today, middle age is generally thought to be roughly 40 to 60 years of age, and the term *elderly* typically refers to those 65 and older. These ages are quite a bit older than a few decades ago. In another few decades, the ages associated with "middle age" and "elderly" are likely to be considerably older as well.
- After the early 20s, there are multiple patterns of decline in the human body. Muscle strength drops to an ever-increasing extent in the later years, bone density drops, and most physiological organs show a reduction in their functional capacities. Sensory receptors also tend to decline in sensitivity, especially those of vision and hearing.
- Several hypotheses as to why we age are still under active investigation, with no clear answer yet emerging. One view is that metabolic processes may leave by-products that decrease the efficiency of proteins and metabolic structures. Another view is that cells may be able to divide only a limited number of times. A third view is that DNA may slowly degrade over time because of mutations.

Cognitive Changes in Adulthood

- While there are some declines in psychological capacities that occur in older adults, there are also areas of psychological performance (for example, some cognitive and emotional abilities) that remain the same or improve in middle and late life.
- Speed of information processing, such as tasks involving simple reaction times, generally shows decline. At the same time, in local areas of high expertise in which tasks are richly structured (through chunking) and highly familiar (through many hours of practice), skill levels may continue to improve for much of the lifespan.
- By selecting a smaller subset of tasks that fit well with successful aging, people can continue to practice and develop an area of expertise throughout much of their life. People can optimize their selected skills, and they can also learn to compensate for losses in one cognitive skill by shifting to a reliance on another that is less affected by aging.
- Memory declines with age, but not in a global manner. Some aspects of memory—especially explicit recall of situations—show substantial declines, while others—for example, more implicit memories driven by frequency and familiarity—stay more constant. Similarly, fluid intelligence—which involves reasoning and processing new information—often shows declines, but crystallized intelligence—which involves familiar facts and knowledge—tends to remain strong in older adults.
- Some aspects of memory, such as prospective memory, which is memory to do a task or obtain a goal, actually show improvement with age. But older adults may have more difficulty than younger adults with source monitoring, often not knowing where they first learned something. This may be because of the relative sparing of semantic memory (memory of a fact) but the decline in episodic memory (memory of the event in which a fact was learned).
- Patterns of reasoning show subtle shifts. In tasks that require equal weighing of several factors or considering additional but irrelevant information, older people can sometimes reason more accurately than younger adults. Older adults also can show better decision making in some emotion-laden situations.
- Circadian rhythms are cyclical surges in hormones and transmitters throughout the day that lead most middle-aged and older adults to have optimal cognitive functioning in the morning hours and most younger adults to show optimal cognitive functioning later in the day.
- Activities, both cognitive and physical, can have a substantial effect on the quality of life as we get older. Physical exercise can greatly slow down many forms of age-related cognitive declines, especially those concerned with higher levels of cognition. Cognitive activity—for example, doing puzzles and

playing card games or word games—can also help maintain mental abilities, although often the positive effects are limited to the task that is practiced and to highly similar ones. With cognitively complex tasks, cognitive reserve may help to preserve memories by providing multiple links to the memories. Moreover, diet restriction has been claimed by some to increase longevity, as well as to improve cognitive functioning.

Changes in Personality in the Lifespan: Individual and Group Changes

- In the realm of personality, there is considerable evidence for continuity of a person's personality traits relative to his peers. Thus, a shy person relative to his peers is likely to stay that way throughout the lifespan. Nonetheless, specific personality traits are not rigidly set by age 30; rather, they continue to be affected by the social environment in which a person spends his life.
- Relatively constant personalities do not mean relatively constant beliefs; individuals can show dramatic changes in beliefs and attitudes as a result of life experiences.
- There are certain group changes in personality in the later decades of life. One such change is toward a positivity bias, in which older adults tend to experience current situations and remember past situations in a more positive manner than younger adults.

Stages of Life?

- There are several theories of stage-like changes throughout the lifespan, changes that can be seen as having an influence on personality. Erik Erikson's theory of psychosocial development has been one of the most dominant theories of this sort. If challenges at each stage are successfully resolved, that stage will form a good foundation for the next stage.
- While stage theories have not been the subject of extensive empirical investigations, some of the patterns they describe are almost surely the consequences of how culture and the process of raising a family or building a career can influence the major conflicts of a person's life. These cultural influences have changed considerably in the past century and will likely change in important ways in the decades to come.

What Does It Mean to Be Old?

- What it means to be old has changed greatly, as increased lifespan, greater variety of career paths, and improved health care have all influenced patterns of aging.
- Ageism and negative stereotypes of the elderly are powerful, often inaccurate, and surprisingly consistent across cultures. They can result in older individuals being discriminated against in the workplace. They can also be the basis for negative attributions during social interactions and for failures in communication. Given the enormous variation in patterns of aging across individuals, stereotypes of the elderly can be particularly distortionary.

THOUGHT QUESTIONS

1. In most countries, there are no age or competency limits on the rights of the elderly to vote in elections, yet there is clear evidence that some older adults vote in highly confused states, sometimes thinking they are voting for candidates from earlier decades. Discuss the tradeoffs in trying to develop a method for screening potential voters in terms of their ability to understand who the candidates are and what their positions are, and using that screening device to exclude elderly individuals with severe dementia.
2. In light of the full body of research covered in this chapter, evaluate the reasonableness of laws specifying that heads of state cannot be younger than certain ages, such as 35 years old. Are such laws reasonable ways to protect countries from risks associated with younger leaders, or are they based on unreasonable stereotypes about younger adults?
3. If a majority of children born today in developed countries were to live past 100, what would be some of the most important consequences for those countries as a whole? How, for example, would health care insurance, the workplace, and career opportunities for younger adults be influenced?
4. Imagine that you are asked to design ideal professional jobs for two outstanding groups of individuals: a group of 30-year-olds and a group of 60-year-olds. How might you design the two positions differently so as to maximize the potential of individuals in each group?
5. Given that most college students are at peak cognitive performance levels in the afternoon or evening and that most older professors are at peak cognitive levels in the morning, how might you adjust teaching and examination schedules to make teaching and assessment most effective?

KEY TERMS

ageism (p. 654)
attraction effect (p. 639)
Big Five (p. 643)
circadian rhythm (p. 641)
cognitive reserve (p. 641)
compensation (p. 637)
complex reaction time (p. 635)
factor analysis (p. 643)
Hayflick limit (p. 632)
optimization (p. 637)
pathological aging (p. 630)
positivity bias (p. 645)
prospective memory (p. 638)
psychosocial conflict (p. 649)
psychobiomarker (p. 632)
simple reaction time (p. 635)
successful aging (p. 630)
telomerase (p. 632)
telomere (p. 632)

Epilogue

After 17 chapters, it is helpful to remind students about the broader picture and to consider why the study of development is so important. It is all too easy to get so immersed in the many details of development that some of the broader messages can be missed or forgotten. The reader is therefore invited to take just a moment or two to think about how the content of this book might make a difference to his or her own life.

What do I hope students will take away from this text? I hope that they will have some enduring sense of developmental patterns, such as how language unfolds over time or how peer relations emerge. They should have a sense of what changes and what doesn't change over time with respect to knowledge and skills in various domains such as mathematical understanding or the self-concept. They should be familiar with some of the grand theories and models of development, such as the debates between nativists and empiricists, or the debates between stage theorists and those who see more developmental continuity. Moreover, in all these cases, I hope that students remember enough concrete examples of developmental phenomena and experimental studies so that they can form the basis for their own views of what develops and why. But, most importantly, I hope that students take away four things:

1. *An ability to evaluate arguments about children.* It is important to be able to critically evaluate arguments about children. The arguments can range from claims about the effects of video games on cognitive development to the position that teenagers should be treated as adults in criminal cases. They can be arguments about the benefits of funding preschool education programs for disadvantaged children to claims about the rights of 18-year-olds to drink alcohol. Whether we have our own children or simply want to curb adolescent misbehavior at the local mall, there are clear benefits in being able to evaluate in a sophisticated and data-driven way arguments about children.
2. *A sense of how children develop and how they fit into broader contexts.* Ten years from now, most students will not remember many fine-grained details from this text. But it is more reasonable to hope that they may remember some larger-scale developmental patterns and what they mean. The seven themes described in the preface (the centrality of feedback loops, development as a dynamic exploratory process, development as constrained by factors that arise both internally from within the child and externally from the environment, a focus on what children can do and not their deficits, viewing infants and children as having some viable version of a skill throughout development, the ever-present links and interdependencies between different areas of development, and seeing developmental psychology as not just a human-based process) are good examples of ideas that might be retained over the longer term. There are also important general impressions about the problems that children confront at different ages and how they tend to solve them. In addition, it is important to remember the different nested communities in which a child develops and how each can have its own special influences. Finally, all of these patterns can help us better understand our own developmental journey and even a bit about our likely developmental future. Doing so will also enable us to better understand the different facets of being an adult.
3. *An appreciation of the sheer beauty and complexity of development.* Even if there were no social policy implications of having a better understanding of psychological development (of which there most assuredly are), it is worth studying developmental psychology simply for the sake of appreciating a remarkable story. For example, when we come to understand the extraordinary complexity of language and that a child masters much of that complexity in just a few short years, that developmental achievement becomes all the more extraordinary. It easily rivals the complexity and beauty of any account of the cellular machinery studied by the molecular biologist or of the origins of the universe by an astrophysicist. By studying such cases as language acquisition in detail, even though such development is commonplace throughout the world, we will never take them for granted again. Instead, we can see not only the marvels in all the things that children come to do, but also in all that adults can do as well.

4. *How a better understanding of children helps create a better future.* All of us, not just parents, live on in the generations that follow us. Our ideas, our values, and all our positive contributions can only be carried forth after our deaths if those who come after us choose to carry them forward. After their parents are gone, most children will not simply live according to a preordained plan laid down by their parents, and most did not do so when their parents were alive. Moreover, as we have seen, parents do not create or sculpt a child into a desired form. Instead, if things go well, they work as mentors, coaches, and partners with children, helping them develop in the most optimal way possible. To better understand children is to know their likely trajectories and to know how our own lives may be partially carried forth in those trajectories. It is to appreciate children as individuals in their own right and to see their nobler goals and beliefs. If we can live our own lives in ways that are aligned with our children's optimal futures and if we do our best to help them achieve those futures, all our good works can be carried forth long after we are gone. In this way, to better understand children is to give much more meaning to our own lives.

If some versions of these four insights resonate with students who have worked through this text, they will have learned a great deal not just about developmental psychology but also about its relevance to a much wider range of intellectual and social issues. On an almost daily basis, I am still struck by new ways in which these insights influence my own interpretations of the world around me.

Glossary

accommodation The process by which the child adapts her cognitive and behavioral structures or schemes to more accurately fit with a pattern in the environment.

action potential A wave of changing electrical potentials that travels down the axon, which is a neuron's main path of transmission.

adaptation In Piaget's sense, a process by which the child better fits her schemes with new experiences in the environment.

affective blunting Showing a low level of expression of emotion, and thought to be a developmental precursor of schizophrenia.

affordances The possibilities for action based on the properties of the objects or surfaces on which the action will be performed. The same object may have different affordances for different organisms.

ageism A form of bias against elderly people that can result in unfair discrimination against them in a manner analogous to cases of racism and sexism.

alerting Arousing the attentional system through a cue that both indicates that a target stimulus is about to occur and that gives some information about the target.

allele A gene variant.

allocentric representation A representation of space that is objective and not relative to the position of the viewer.

altruism Behavior in which an individual acts for the benefit of another at his or her own personal expense.

amenorrhea The absence of a menstrual period in women who are of menstrual age. This often occurs in those with anorexia nervosa.

amygdala A brain structure that is located near the brain's midline in the right and left temporal lobes and that is involved in the manifestation and regulation of emotions.

analogical reasoning A way of comparing things that, on the surface, seem quite different in order to see deeper level similarities between them.

animism According to Piaget, the tendency of young children to attribute psychological motivations to nonliving things.

anorexia nervosa An eating disorder characterized by an intentional refusal to eat anything beyond minimal amounts of food as well as by an excessive concern with being thin.

anorexic family A family in which a certain pattern of interaction is thought to foster the emergence of anorexia.

A-not-B error The tendency of infants to search for an object where it has previously been found and not where it was most recently observed to be hidden.

antisocial behavior Behavior that hurts or impairs another individual or a group. Such behavior can include both verbal and physical aggression as well as cheating and lying.

anxiety disorder A disorder in which anxiety is so strong and persistent that it interferes with normal functioning. Anxiety disorders include phobias, social anxiety disorder, generalized anxiety disorder, and obsessive-compulsive disorder.

anxious attachment *See* insecure/resistant attachment.

aphasia A form of brain damage that causes problems in language function. There are different kinds of aphasias that impair different aspects of language.

apoptosis Programmed cell death that occurs in the course of normal neural development.

aptitude-treatment interaction Relationship between the effectiveness of a particular teaching method (treatment) and the learner's specific strengths (aptitudes) and weaknesses; often known as "learner characteristics."

assimilation The process by which the child incorporates new information from the environment into his preexisting mental structures or schemes in a way that usually distorts the new information to fit with the preexisting structures.

astigmatism A visual condition that affects the focusing of light and results in stimuli at different orientations being perceived with different levels of acuity.

attachment The strong and enduring emotional bond between a child and a significant other and the processes that create and maintain this long-lasting social relationship.

attachment complex The set of behaviors and mental states that, taken together, are responsible for setting up and maintaining attachment.

attachment style A pattern of relating to significant others based on expectations about how they will respond and affecting perceptions, emotions, thoughts, and behaviors in close relationships.

attention-deficit/hyperactivity disorder (ADHD) A constellation of problems resulting in difficulty staying on task, often accompanied by restless activity.

attentional deployment A method of emotional regulation that involves purposely shifting the focus of one's thoughts in a way that makes a situation feel less emotionally charged.

attentional schema A cognitive structure that is learned through experience in response to a particular set of stimuli in a specific kind of task. When embedded in such tasks, attentional schema form a framework for organizing information and responses to that information and for recognizing particular patterns of information and filtering out irrelevant information.

attraction effect An effect in judgment and reasoning in which people tend to change their estimates of the values of goods in the face of additional, but irrelevant, information.

attribution theory A theory that encompasses the way that people explain their own behavior and the behavior of others.

authoritarian parent A parent who adopts a stern, coercive mode of child rearing.

authoritative parent A parent who adopts a warm mode of child rearing with clear limits and guidelines for the child's behavior.

autism A disorder characterized by difficulty relating to others that generally appears before age 3. It is usually associated with a lack of empathy, problems with social responsiveness, language and communication deficits, and resistance to changes in routine, and it often includes repeated stereotyped movements and a narrow focus of interest.

autobiographical memories Explicit memories of specific experiences in one's own life.

autonomous stage In Piaget's theory of moral development, a stage in which children think of rules as social conventions that are created by humans and can be changed by humans.

avoidant attachment *See* insecure/avoidant attachment.

axon Tubelike projection from the neuron along which the action potential travels and which ends in an axon terminal containing neurotransmitters that will be transmitted to another neuron.

babbling Part of the sequence of prelinguistic vocalizations occurring in the first year of life. Children go through increasingly complex patterns of babbling, starting from around 4 months onward. Deaf children show a comparable babbling with sign language.

baby sib study A study in which younger siblings of children who have a disorder are studied for signs of early precursors of the disorder. If there is a substantial heritability to the disease, the younger siblings are much more likely to develop the disorder than the general population of young children, making the odds of discovering early precursors higher.

base pair A pair of complementary bases (adenine with thymine; guanine with cytosine) in DNA.

basic emotion An emotion, such as joy, sadness, disgust, surprise, fear, or anger, that is thought to be present in young infants and that is one of the building blocks for the emergence of later more complex emotions; also referred to as a primary emotion.

basic level of categorization A level of categorization at which category members maximally contrast with members of other categories while also having high similarity among members of the same categories.

behavioral genetics The study of how genetic variation between individuals or populations in a species contributes to behavioral variation.

behavioral genomics The study of genetic variation in a species' genome and its effects at the molecular level and links between those molecular effects and behavioral variations.

behaviorism The view that psychology is best understood as describing the effects of external contingencies on behavior and not by referring to unseen mental events and representations.

bell curve A plot of the distribution of scores in a large population; also known as a normal distribution curve.

between-subjects design A design in which different but equivalent groups are assessed in each experimental condition in a study.

Big Five Relatively independent clusters of five personality traits—extroversion, neuroticism, openness to experience, agreeableness, and conscientiousness—that have repeatedly been shown to have strong genetic bases.

bilateral symmetry Symmetry of structures around both sides of a center line, such as right and left kidneys, arms, legs, eyes, and ears.

binocular cue A cue to the perception of depth that arises from the use of both eyes.

binocular disparity *See* binocular parallax.

binocular parallax A binocular cue to depth that arises from small disparities between the images that reach the two eyes; also called binocular disparity

bipolar disorder A distinct affective disorder that is characterized by swings between periods of lethargy and low affect and periods of high activity, or "mania," in which the person often has inflated self-esteem, grandiose plans, increased talkativeness, and a diminished amount of sleep.

blended family A family consisting of the parents and all children from their current relationship as well as children from prior relationships.

blocking A phenomenon in classical conditioning in which pretraining with one conditioned stimulus can interfere with (block) the formation of an association with a subsequent conditioned stimulus.

bootstrapping Building new conceptual structures out of earlier ones that serve as a framework for fostering conceptual change and growth.

brainstem A structure beneath the brain and above the spinal cord that is concerned with regulating heart rate, breathing, swallowing, blood pressure, digestion, and other automatic nonvoluntary processes in the body.

branching direction Language structure in which the hierarchical embeddings of grammatical categories branch in a particular direction. Different languages have strong tendencies to be either right branching or left branching.

bulimia nervosa An eating disorder in which a person eats excessively and rapidly and then follows those episodes of overeating with some way of purging the food.

bullying Repeated and sustained verbal or physical threats or attacks against a victim who is unable to defend himself or herself. Also known as peer victimization.

canalization The process in which cells get committed to becoming certain cell types over the course of development.

catastrophizing Assuming the worst possible outcome for future events, even when those outcomes are highly unlikely or implausible.

categorical perception The tendency to group stimuli that vary along a physical continuum, such as light wavelength, in terms of categories, such as different colors.

catharsis hypothesis The hypothesis that experiencing aggression in a pretend setting (such as watching a violent television program) releases aggressive impulses so that such impulses are less likely to be released later. This hypothesis was popularized by Freud and then extended by those trying to minimize the impact of television violence. With respect to viewing violence on television, this hypothesis is, with only rare exceptions, false.

centration A mental operation, according to Piaget, that emerges in the preoperational period and that causes the child to focus on one dimension (for example, height) while ignoring relevant other dimensions (for example, width).

cephalocaudal development Development in which the more anterior sections mature earlier than the posterior sections (cephalo = head, caudal = tail).

cerebellum A brain structure beneath the rear end of the cerebral cortex that is involved in coordination of voluntary movement and integration of some sensory information with action.

cerebral cortex The region of the brain associated with high-level thought and perception. It is commonly divided into four major regions on each side of the brain: the frontal, parietal, temporal, and occipital lobes.

cerebrum A complex of three structures in the brain, consisting of the basal ganglia, the olfactory bulb, and the cerebral cortex.

characteristic feature In the study of word meaning, a feature that is typically associated with members of a category but that is not essential to any members of the category.

child effect A genetically determined behavior in a child that evokes a particular kind of behavioral response in the parent.

child-directed speech Speech by adults or older children that is directed toward younger children and that is altered in a wide variety of ways (for example, slower, louder, and higher-pitched speech that stresses the boundaries between words) that make it different from speech directed toward adult peers; also known as motherese and infant-directed speech.

chromosome An organized cluster of genes within the cell nucleus. The chromosomes contain the cell's DNA.

circadian rhythm Daily cycle of biological function and activity based on the rise and fall of hormones and neurotransmitters in an organism over the course of a 24-hour period.

classical conditioning A form of learning in which the pairing of an unconditioned stimulus with a conditioned stimulus results in a conditioned response.

classification In Piaget's theory, the ability to think about groups of things as forming classes defined by a single property or relation.

class-inclusion relations How different classes of things in a hierarchy relate to each other and how broad superordinate categories can encompass narrower, subordinate categories.

clique A small group of peers who voluntarily spend a great deal of time together and seem to actively exclude others.

codominant Referring to a case where two different alleles for a gene are both expressed phenotypically.

cognitive empathy A form of empathy that requires social cognitive skills and the ability to take another's perspective and that involves understanding and representing the emotional and mental points of view of others.

cognitive map A mental representation of the spatial layout, used to infer distance, direction, and a way of navigating the environment.

cognitive reserve Psychological capacity that is available to support cognitive functioning in the face of age-associated declines or minor brain injuries.

cognitive-behavioral therapy (CBT) A therapy that is based on the idea that a person's problems stem from how he sees and thinks about the world and that the way to change the behaviors is to change the ways the person interprets and thinks about the world around him.

cohort effect An effect produced in children of a particular age group based on their experiences in the culture that differ from the experiences of those who are younger or older.

collectivist culture A culture in which the rights of the group are deemed to be more important than the rights of the individual.

compensation The process of mitigating the effects of aging on cognitive performance by introducing aids to cognition or altering behavior.

compensation A mental operation, according to Piaget, that emerges in the concrete operational period and that enables the child to understand how a change in one dimension, such as height, might be compensated for by another change, such as in width, with a third dimension, such as quantity, remaining invariant.

compensation plasticity The capacity for an area of the brain that has been deprived of its normal inputs and processing routines to have heightened functions in other abilities that compensate for the loss.

complex emotion An emotion, such as guilt or pride, that is thought to emerge later in development and that may build on interactions of basic emotions and involve supporting cognitions.

complex reaction time The time taken to engage in a response to various spatial and temporal configurations of stimuli, such as pressing a key when the number following a prior number is twice that prior number.

conceptual self A view of the self that includes a sense of the roles that we occupy in broader cultural and social contexts.

concrete operational period A stage of cognitive development occurring after the preoperational period and before the formal operational period, roughly from 7 to 12 years. During this stage, children start to use mental operators such as identity and reversibility to more flexibly understand the physical world and the ways in which it can change.

conditioned response (CR) A response that becomes associated with a stimulus that normally does not elicit that response.

conditioned stimulus (CS) A stimulus that becomes associated with an unconditioned stimulus (and its response) but that would not normally elicit a response.

conduct disorder A pattern of frequent and recurring antisocial behaviors in children and adolescents, whereby the children regularly violate the rights of others as well as violating social norms or rules.

confluence theory The theory that as family size grows, there is a corresponding drop in the overall intellectual climate in the family because many conversations and interactions would be between children rather than between adults and children.

connectionism An approach to learning and representation that posits massively parallel processing of small elements, none of which by themselves may be explicitly represented. This approach draws heavily on statistical patterns of feature correlations in the environment.

conservation task Any of the tasks designed by Piaget in which children are asked to judge whether certain physical properties of an object, such as its size, or aspects of an array, such as its number, remain unchanged when the object or array is transformed along different dimensions.

constraints on word meanings Constraints on the possible meanings that can be assigned to a given word. These are thought to be necessary to explain how word meanings are acquired because they narrow down the enormous number of possible meanings to a workable number.

constructivist approach An approach to moral development that sees the child as constructing moral interpretations of a situation by evaluating the situation, the actors, and the cultural context.

controversial child When sociometric status is measured, a child classified as high on both the like and the dislike scales. Controversial children are noticed by everyone and are seen as sociable and as leaders, but they are also more likely to be seen as aggressive and arrogant.

convergence A binocular cue to depth that arises from the sensation that occurs when the two eyes converge to focus on an object.

converging methods Using various approaches to study a problem from different vantage points in order to arrive at a more accurate, objective answer than any single method could produce alone.

core domain A domain of knowledge and thought that is thought to have a privileged role in development, emerging early in infancy and maintaining a strong influence throughout much of development.

corpus callosum A central pathway made up of a large set of heavily myelinated nerve fibers that transfers information between the two hemispheres of the cerebral cortex.

co-rumination The tendency for a social group to dwell on negative events in a mutually reinforcing manner.

creativity The ability to come up with ideas or strategies that are both novel and truly original as well as being useful or functional.

critical period A period in development when a particular experience may have a dramatic impact and during which learning a particular kind of information or skill is possible. Before or after such a period, experience barely seems to have an effect and learning does not occur.

crossing-over A recombination of genetic material from the father and the mother that occurs when part of one chromosome switches locations with the corresponding part of the other chromosome in the pair.

cross-sectional approach An approach to development in which studies look at different groups of participants at different age periods.

crystallized intelligence The ability to use specific skills and knowledge gained through experience.

cueing hypothesis An explanation of infantile amnesia that is based on the idea that early memories are present but not available unless linked to the right sorts of cues.

cultural psychology A view of psychology in which cultural differences are believed to greatly influence psychological processes and representations. This view argues against the existence of intrinsic universals of moral thought.

culture of honor A cultural style, seen in the American South, in which there is an endorsement of relatively higher levels of violence in response to threats to oneself, one's property, or one's background. (It does not endorse more violence in all situations.)

cyberbullying A form of aggression over the Internet, usually in which a group victimizes an individual.

cycle of abuse The pattern in which abused children grow up to be abusing parents, whose abused children then grow up to abuse their children.

declarative memory Memory that can be described as "knowing that," such as knowing a fact or that an event has occurred; sometimes used synonymously with explicit memory.

defining feature In the study of word meaning, a feature that is necessary to specifying meaning.

delay of gratification The ability to hold off engaging in an action that will bring a desired reward.

delusion A false or highly unrealistic belief. Delusions are often evidence of psychosis and frequently a symptom of schizophrenia.

dendrite One of many signal-receiving branches extending from a nerve cell. Dendrites contain terminals that respond to specific neurotransmitters from other neurons and conduct the information received toward the cell body. As many as 10,000 dendrites may be present per neuron.

dependency A reliance on another for basic physiological needs, such as food and shelter and protection from harm. Attachment and dependency can be largely dissociated.

dependent variable The variable that one is measuring in a study to see how it varies as a function of different values of the independent variables, which are manipulated as a way of exploring and explaining the nature of the dependent variable.

depressogenic vulnerability The convergence of the separate cognitive, biological, and emotional factors to create depression.

desensitization A process in which experiencing continuous high levels of violence comes to be accepted as normal and may lead to increased tolerance of aggressive behaviors as well as increased willingness to engage in aggressive acts.

developmental intergroup theory A theory that children as young as 4 years of age start to notice perceptually salient group differences and to attach these to stereotypes.

diathesis-stress hypothesis The proposal that a genetic predisposition for a mental disorder may combine with high levels of environmental stress to cause the disorder to become manifested.

dishabituation The expression of interest in a new display or scene, as shown by increased responses to the novel stimulus.

disorganized attachment An attachment style marked by less consistency across situations and characterized by combinations of both insecure and controlling behaviors. Infants showing this style may have a higher incidence of psychopathology in later life.

display rules Norms governing the kinds of emotional expressions a particular group considers appropriate in particular situations.

dispositional factor A factor intrinsic to a person, such as a trait or the person's temperament.

dizygotic (DZ) twins Twins from two different zygotes; often referred to as fraternal twins.

DNA Deoxyribonucleic acid, normally found in cell nuclei; contains the molecular code in the form of sequences of chemical bases (adenine, thymine, guanine, and cytosine) for cellular construction and growth.

domain general Referring to a learning mechanism or representational format that applies across all domains of cognition.

domain specific Referring to a learning mechanism or representational format that applies to a specific domain of cognition.

dominance hierarchy A network of relations between members of a social group, often primates. The structure of the network often involves a single powerful individual at the top and groups of subordinates that get ever larger with decreasing social status.

dominant Referring to an allele that is expressed in the phenotype, both when paired in a homozygous pair of alleles and when paired with a recessive allele in a heterozygous pair of alleles.

dual representations Models that can be both physical objects in their own right and also symbols for other objects.

dynamic cue A cue to the perception of depth that arises from moving objects and surfaces.

dynamic systems theory A theory of motor development that stresses the importance of the physics of the limb and the environment in which an action is made in addition to central cortical control programs.

dyslexia A learning disability typically involving a deficit in phonological processing despite normal intelligence, a good motivation to learn to read, and ample early exposure to environments that normally foster reading.

ecological self A sense of the self as moving through the world, gained through perception and action.

ecological systems approach An approach to the study of families that emphasizes the various contexts in which children develop and how children fit into those contexts.

ecological validity A quality of a study that captures all the critical factors to understanding a behavior or ability in a natural context.

ectoderm One of three cell layers at an early stage of development. Cells from this level become skin, hair, the brain, and the spinal cord.

egg cell The female gamete that merges with the male sperm cell during fertilization.

ego One of three components of the mind described by Freud that normally emerges in development after the id and before the superego and that enables the child to channel and direct the id.

egocentric representation A representation of space that is relative to the position of the viewer.

egocentrism In cognitive development, a tendency to fail to take into account the points of views of others.

elective mutism A phenomenon, often found in autism, in which a child who is capable of speaking almost never does so in social interactions.

embryo The developing organism between the middle of the second week and the end of the eighth week of development. During the embryonic period, rudimentary systems, structures, and organs first appear.

emergent constraint A constraint that emerges over the course of development and that reflects the influences of experience and the environment.

emotion A transient state that corresponds to physiological and cognitive processes associated with distinct internal sensations, or feelings.

emotional contagion A process in which the emotional states of others, such as laughter or sadness, become manifested in a person who is exposed to those states.

emotional empathy A form of empathy that involves directly witnessing another person's emotional state and feeling the same emotion in a relatively immediate and direct way.

emotional intelligence The ability to recognize, think about, and manage our own emotional states and processes as well as recognizing the emotional states of others.

emotional regulation The ways in which people of all ages influence the particular emotions they experience, when and how they experience them, and how they reveal these emotions.

empiricism A view of development that stresses the presence, at birth, of a general, all-purpose learning system, with little or no biases to acquire particular kinds of information.

encoding The process of turning information into a mentally useful representational format.

endoderm One of three cell layers at an early stage of development. Cells from this level become glands and the linings of the lungs.

environmental niche A particular kind of environment that an organism lives in and for which the organism has evolved adaptations that enable it to thrive in that environment.

epigenetic regulation The process in which changes in gene expression occur based on internal and external environmental signals that affect the DNA.

episodic memory Memory of specific events that one has experienced; a type of declarative memory. Autobiographical memories are a kind of episodic memory.

equilibration The process through which a child's mental structures come into a better fit with various aspects of the environment through assimilation and accommodation.

essentialism A tendency to assume that the surface properties of entities are caused by deeper essences.

ethology The study of traits (either body parts or behavior) from an adaptive evolutionary perspective that usually involves comparisons across species.

evaluative reasoning Thinking about an individual's qualities and behaviors in terms of whether the person is entirely good or entirely bad and predicting his future behavior on that basis. (*Compare* trait-based reasoning.)

evidence-based therapy Therapy for which efficacy has been shown by rigorous, carefully controlled studies that compare one therapy with another or with no therapy.

evolutionary psychology A view of psychology that emphasizes evolution of a variety of psychological adaptations that increased the fitness of individuals. In regard to moral development, the emphasis is on the universals of moral thought and behavior that have been selected as adaptive in all humans.

executive functioning The collection of cognitive activities involved in goal-directed tasks and problem solving, including inhibitory control, error correction and shifting, and working memory.

experience-dependent plasticity The phenomenon of changes in brain structure as a result of experience, usually referring to either the creation or elimination of synapses or the creation or death of neurons.

experimental study A study in which a certain variable (the independent variable) is manipulated while holding all other aspects of the experimental situation constant to see how the manipulation affects the dependent variable.

explicit cognition Knowledge or thought processes that are part of conscious awareness and that can often be described in words.

explicit memory Memory for information that involves conscious recall.

extended family A family whose members reach across generations and sometimes incorporates aunts, uncles, and cousins.

extended self A sense of the self as traveling along an autobiographical timeline.

externalizing problem A problems that is expressed externally by a child, such as aggression or sexual promiscuity.

factor analysis A technique in data analysis that isolates relatively independent clusters of information that vary along dimensions known as factors.

false-belief task A task that assesses the ability to understand how others might have beliefs that are contrary to a true state of affairs in the world.

false-photograph task A task developed to investigate whether children who fail false-belief tasks actually misunderstand beliefs per se. The task does not involve beliefs, but young children still have trouble inhibiting a default (incorrect) response based on the objects that are in view when they are questioned.

fast mapping The phenomenon of rapidly learning the mapping between words and the entities they refer to. While specifically proposed for word learning, it seems to be a broader phenomenon that also applies to other forms of mapping.

feedback loop In developmental psychology, the constant interplay between an infant and his environment, in which an experience causes a change in the infant's state, which in turn influences how the infant's next experiences are encountered.

feral child A child who grows up in the wild and has no contact with humans.

fetus The developing organism after the embryonic period, when later prenatal change appears more qualitative. During the fetal period, which occurs from week 9 until birth, organs, muscles, structures, and systems grow larger and mature, developing into recognizable forms.

fixed-trait theorist An individual who tends to think that traits are intrinsic and unchangeable regardless of effort.

fluid intelligence The ability to think flexibly and solve novel problems. It supposedly does not depend significantly on acquired knowledge.

Flynn effect The finding that intelligence test scores have been consistently rising throughout the world for the past 60 years, a pattern that was masked by the changing the norms of the tests.

formal operational period A stage of cognitive development occurring after the concrete stage, at roughly 12 years old but with considerable variability. In this stage, children start to engage in deductive and logical reasoning about situations and processes and are able to consider logical alternatives and their potential consequences.

foundational constraint A constraint that is present from the start and is usually associated with nature accounts of learning and development.

friendship An ongoing, positive reciprocal relationship with a chosen companion.

frontal lobe A lobe in the cerebral cortex involved in planning, problem solving, and the regulation of thought and emotion. More posterior parts of the frontal lobe are also involved in aspects of motor activity and the processing of grammar.

functional fixedness A bias to use an object or device in its traditional manner and not to come up with novel, more creative uses.

functionalist approach An approach to emotion that stresses the function of emotional responses—specifically, that emotions help mobilize us to take action toward goals.

fundamental attribution error The tendency to explain the behavior of others in terms of dispositional factors as opposed to situational factors.

gamete A specialized sex cell from either the male (sperm) or the female (egg) that combines with another sex cell during reproduction.

gastrulation The process of cell differentiation into three primary germ layers: ectoderm, endoderm, and mesoderm.

gender identity A sense of whether we are male or female.

gender role The behaviors and traits that are considered typical of each sex.

gender schema A cognitive structure for interpreting gender-related activities and roles.

gene A section of genetic material with inherited instructions for creating a protein (or part of a protein) and regulating when the protein will be active.

general intelligence, *g* A common factor that seems to be behind performance on the vast majority of items on standardized psychometric tests of analytical intelligence.

generalized anxiety disorder A disorder in which there are high levels of anxiety for a wide range of situations as opposed to the specific fears in phobias.

generativity The degree to which a language is able to generate a large number of novel patterns and structures from a small number of primitives and rules.

genome The entire body of genetic information for an organism, often used to describe the most typical profile for a species or subspecies.

genotype The genetic makeup of a specific individual or a specific gene, encoded as alleles in the individual's DNA.

geometric information The information about an environment's overall shape (its contour) that helps to locate oneself in space.

Gestalt principles Holistic principles of perception that allow viewers to parse up the world into objects and other meaningful units.

glial cell A brain cell that provides nutrients, produces myelin, and provides structural support. Glial cells are roughly 10 times as common as neurons.

global change A type of development that occurs at roughly the same time in very different areas of thought or behavior.

goodness of fit The idea that infants with different temperaments may thrive in different environments that fit best with those particular temperaments.

grammar The structural relations of a language that govern how words and other syntactic units are organized.

grasp reflex A reflex found in newborns in which they will grasp an object when it is pressed against their palm.

growth cone The end of an axon that is migrating through neural tissue to its eventual destination. It guides reactions toward and away from chemical gradients until it arrives at its destination, where it forms a synapse with a target neuron.

habituation The gradual decline of interest in a display or scene, as shown by a decrease in responses to a repeated stimulus.

habituation method A method to determine if an infant can distinguish a new stimulus from a familiar stimulus. An infant's responses (for example, looking time) will decrease with repeated presentation of a familiar stimulus, but they will increase if the infant perceives that there is a new stimulus.

Hayflick limit The view that human cells can only divide roughly 50 times, putting an upper limit on the lifespan of an organism.

heritability The extent to which variations in a trait within a particular population are due to genetic differences rather than environmental differences.

heterochronic gene A gene that is related to the timing of development, often regulating when other genes turn on or off.

heteronomous stage In Piaget's theory of moral development, a stage in which children think that rules are fixed and immutable realities that are part of the natural world.

heterozygous Having two different alleles for a particular gene.

hippocampus Bilateral structures that are involved in developing new memories and that bind information from different brain regions. Bilateral damage may cause difficulty in consciously accessing new memories.

holophrase A single word that stands for a larger phrase or full sentence that is mentally present but that the child is unable to produce.

homeobox A short stretch of 180 base pairs of DNA that occurs in the same precise sequence in many different species and that encodes the proteins that regulate the formation of body regions and structures.

homeobox genes Master-switch genes that contain the homeobox and that affect the body plan of many different species by encoding proteins and regulating gene expression.

homozygous Having the same alleles for a particular gene.

hostile attribution bias A tendency to interpret ambiguous situations as hostile.

Hox genes Homeobox genes in vertebrates. *Hox* genes encode proteins and regulate gene expression and thereby affect the body plan of vertebrates.

hue The aspect of color that is a consequence of wavelengths of light.

hypothetico-deductive reasoning The ability to think systematically about different possibilities that might depart from the current reality and to derive predictions given that certain information is true.

id One of three components of the mind described by Freud that emerges first in development and represents an individual's basic desires and drives.

identity A mental operation, according to Piaget, that emerges in the concrete operational period and that enables the child to realize that a single dimension or aspect remains the same despite dramatic changes in other dimensions.

idiographic approach With respect to creativity, studying case histories of highly creative individuals to see whether they seem to cluster into different types.

imaginary companion A fantasized character that a child makes up or an object that the child treats as an animate creature.

immanent justice In Piaget's theory of moral development, a form of reasoning about justice in which the child believes that most events that adversely affect an individual who has previously done something wrong are forms of punishment for the earlier transgression.

impersonal moral situation A moral situation in which the individuals involved are not salient and in which it is possible to adopt a moral stance that appeals to abstract moral principles and patterns of reasoning.

implicit cognition Knowledge that exists outside of awareness and that may be difficult to describe in words.

implicit memory Memory for information or actions that occurs outside of conscious awareness.

imprinting A form of learning that takes place during a critical period in which young members of a species acquire a behavior or response pattern that remains permanent after the critical period is over.

incremental theorist Someone who views traits as changeable through effort.

independent variable A variable that one manipulates so as to understand patterns of variation in the dependent variable.

indiscriminate attachment An attachment style in which infants are as affectionate and receptive to complete strangers as they are to their primary caregivers.

individualist culture A culture in which the rights of the individual are deemed to be more important than the rights of the group.

infantile amnesia The inability to recall any memories prior to a certain age, usually around 2½ years of age.

information integration theory A theory of cognitive development that says that older children integrate different dimensions or components of a task into a coherent system for successful reasoning, whereas younger children focus excessively on one dimension or component of the task at the expense of others.

inimical relationship A relationships characterized by conflict, dislike, and aggression in which each person considers the other to be an enemy.

insecure/avoidant attachment An attachment style in which infants not only avoid or fail to initiate interactions with the mother after a reunion, but also show less visible anxiety in the absence of the mother.

insecure/resistant attachment An attachment style in which infants show elevated anxiety in the absence of the mother and often try to vigorously prevent her from leaving. They may also show distress and anger when the mother returns while nonetheless clinging to her. In the presence of a mother and a stranger, they may explore minimally and be quite clingy. Also known as anxious attachment.

instrumental conditioning *See* operant conditioning.

instrumental helping Prosocial behavior to help someone else achieve a goal, even though there is no obvious benefit to the helper.

intelligence quotient (IQ) Originally an index of intelligence based on the ratio of a person's mental age to his chronological age. IQ is now calculated in a different manner and simply refers to where a specific score stands on a distribution of intelligence test scores.

intermodal perception The ability to see objects and events in an integrated manner across different sensory systems, such as vision and hearing.

internal working model A mental representation of the self and others and how they might interact in different circumstances.

internalizing problem A problem that is largely within the individual, such as depression.

interpersonal intelligence The ability to have empathy and to think about factors governing interactions between people; a form of emotional intelligence.

interpersonal self A sense of the self as engaged in social interactions with others.

intrapersonal intelligence The ability to think about factors governing our own mental, social, and emotional states; a form of emotional intelligence.

invisible displacement The movement of an object to a new hiding spot when it is covered by another object and therefore not directly visible.

joint attention The situation in which two people are jointly attending to an object and are aware that they are both doing so.

kinesthetic self-concept A concept of the self that arises from an awareness of our motor actions as we moves in an environment.

landmark A large object in the environment that enables an organism to navigate by estimating distance and direction from the landmark.

language acquisition device (LAD) A hypothesized mental system in humans that is specialized for the acquisition of language and not other kinds of knowledge.

latency period A time in middle to late childhood, posited by Freud, when children tend to practice strict segregation of the sexes in terms of preferred playmates and friends.

learned helplessness A learned state in which an organism concludes that escape from an aversive situation is impossible and that it is helpless and cannot change things for the better.

lexicon The set of words that a person knows; often referred to as a person's vocabulary.

linguistic determinism The view, first attributed to Whorf and Sapir, that the language that one learns determines the nature of one's thoughts.

linguistic relativity The view, first attributed to Whorf and Sapir, that patterns of thought vary as a function of the language one learns.

local change A specific psychological capacity that develops relatively independently of other specific capacities.

longitudinal approach An approach to development in which studies look at the same group of participants at different age periods.

long-term memory Memory that endures for extended periods of time. Information in long-term memory has often been processed, organized in terms of meaning, and stored for later retrieval.

Machiavellian emotion An emotional expression that is used to produce an effect in others and that does not necessarily reflect the emotion actually felt by the agent expressing it.

maturational account An account of development in which developmental change is largely attributed to biological maturation as opposed to experience.

meiosis The process in which certain types of cells divide and produce cells with single sets of chromosomes. The correct chromosome number is once again restored during sexual reproduction.

memory format change hypothesis An explanation of infantile amnesia that is based on the idea that infants and very young children represent the world in a format that is radically different from later formats and is therefore inaccessible at later ages.

mesoderm One of three cell layers at an early stage of development. Cells from this level become muscles, organs, and skeleton.

meta-analysis A technique of data analysis in which data from multiple prior studies are gathered into a large-scale study and the data are statistically analyzed to determine which treatments are most effective.

metacognition Knowledge about the nature of one's own mind and thoughts and those of others.

metamemory A form of metacognition involving knowledge about what memory is, how it works, and what its limits are.

methylation A process in which methyl groups become attached to certain DNA base pairs, usually with the result of turning off genes that follow them in a regulatory sequence.

microgenetic analysis A study in which the researcher monitors the process of development by assessing participants every few days or weeks rather than every few years.

migration The process by which cells in a developing organism move to their eventual permanent destinations.

mirror neuron A neuron in the brain that is activated both when performing an action and when perceiving it being performed by others and that is thought to support imitation.

mirror test A test of someone's sense of self in which a mark is put on a subject such that it can only be seen when the subject views himself in a mirror.

mitosis The normal process of cell division in which genetic material is conserved.

modeling theory An approach to learning and socialization based on the idea that children and adults reproduce behaviors that they observe others performing; also called social learning theory.

module In Fodor's sense, a functionally specialized cognitive system that is tailored for processing certain forms of information in ways that are not influenced by other cognitive systems.

monozygotic (MZ) twins Twins from the same zygote; often referred to as identical twins.

moral dilemma Devised by Kohlberg to study moral reasoning, an ambiguous situation in which a person in a story must make a difficult moral decision and the participant in the study must say which choice is better and why. The pattern of reasoning used by the participant is more important than the actual choice selected.

moral dumbfounding The finding that in some moral situations, people have strong convictions about what is right and wrong but are unable to explain why.

moral modules Forms of moral reasoning that have evolved to deal with specific kinds of moral problems encountered by individuals and groups.

Moro reflex A reflex found in young infants in which an abrupt lack of support of the head results in an outward and upward movement of the arms.

morpheme The smallest unit of language that represents a discrete meaning. Morphemes are not only words but also parts of words that carry meaning, such as plural endings in English.

motherese *See* child-directed speech.

motion parallax A cue to depth that arises from the relative motion of objects at different distances.

motor deprivation A condition under which an organism is either prevented from moving or not given the opportunity to pair movement with perception or objects acted upon.

motor empathy A form of empathy in which a person tends to automatically copy the motor actions, postures, and facial expressions of another.

multiple intelligences The theory that intelligence is divided into eight distinct modalities that often have strong sensory or motor links.

mutual antipathy A pattern found in both bully-victim relationships and inimical relationships in which two children intensely dislike each other.

mutual exclusivity A constraint on word meanings based on the assumption that entities do not tend to have more than one label.

myelin A fatty substance that wraps around the axons of neurons and speeds up the transmission of action potentials.

myelination The process by which the axons of neurons are enclosed in a myelin sheath.

nativism A view of development that stresses the existence, at birth, of a set of different learning systems, each biased to acquire particular kinds of information better than others.

natural language A language that can be learned and used easily and relatively effortlessly by young humans.

negativity bias A bias to pay more attention to and/or weigh more heavily negative rather than positive information.

neglected child A child who does not appear to be high on either the like or dislike scale of an assessment of sociometric status. Neglected children are often shy and withdrawn, and they are largely ignored by their peers.

neural change hypothesis An explanation of infantile amnesia based on the idea that early memories do not become permanent because of intrinsic immaturities of the child's brain that make it initially unable to store information for the long term.

neural tube The round, enclosed structure that is usually formed in the first few weeks of life and that encases the spinal cord and the brain.

neurogenesis The making of new neurons, usually prenatally, in humans.

neuron A brain cell containing a cell body, axon, and dendrites; also known as a nerve cell. Brain cells communicate with other cells both within the brain and from other parts of the body.

neurotransmitter A chemical that mediates transmission of impulses across synapses.

neurulation The formation of the neural tube through closing of the neural plate.

nomothetic approach With respect to creativity, comparing the lives of especially creative individuals to look for common patterns or principles.

normal distribution curve A plot of the distribution of scores in a large population; also known as a bell curve.

nuclear family A family typically consisting of the mother and father as heads of the household, along with their children.

object concept A concept of the behavior of a bounded physical object, which is generally studied under certain conditions of change, such as when it disappears from view.

object permanence The property that objects continue to exist even when they are out of sight.

object solidity An object's property of cohering and taking up space, preventing other objects from passing through it.

observational study A study in which the researcher simply observes participants acting in various contexts.

obsessive-compulsive disorder (OCD) A disorder involving a high level of anxiety about contamination, order, loss of objects, or aggressive or sexual thoughts and characterized by persistent, intrusive thoughts and highly repetitive checking behaviors.

occipital lobe A lobe in the cerebral cortex that has structures primarily concerned with processing visual information at various levels of increasing complexity.

operant conditioning A form of learning in which desired behaviors are gradually approximated in an organism through schedules of positive and negative reinforcement for increasingly accurate versions of the desired behavior; also called instrumental conditioning.

operator A formal mental tool by which people mentally represent states and changes in the world.

optimization The continued perfection of a skill through hours and hours of diligent practice; often a way in which older adults can do better than younger adults, who are faster on simple reaction times for all components of the skill.

optokinetic nystagmus method A technique used to measure acuity, in which increasingly thin arrays of stripes are moved across the infant's visual field and the infant's spontaneous eye tracking of the stripes is observed.

orienting Drawing attention to a particular area so that a person can recognize when a stimulus occurs.

overextension A phenomenon in semantic development in which the child uses a word to apply to a larger set of entities than is normal in adult usage.

overjustification effect A drop in spontaneous behavior due to reduced motivation, produced when we perceive the behavior as having been done for an external award.

overregularization The excessive use of a rule so that it applies to more cases than it actually should.

oxytocin A hormone that leads to increased levels of trust and nurturance to members of one's group.

parenting style The behaviors and attitudes that parents have toward their children, which together create a particular parenting environment or climate.

parietal lobe A lobe in the cerebral cortex that has several functions, including processing and interpreting touch sensations, integrating visual and spatial information, and processing some aspects of the semantic properties of language.

patellar reflex An early-emerging reflex, also known as the "knee jerk reflex," involving the extension of the lower leg when the tendon at the kneecap (the patella) is abruptly pressed.

pathological aging A pattern of aging that reflects the effects of other physiological or mental diseases or of extreme environmental influences.

peer nomination A process of measuring sociometric status or popularity by asking peers to name other children who they like the most and the least or want to be friends with the most and the least. Peer nominations are often asymmetrical.

peer victimization *See* bullying.

perceptual narrowing A process in which infants increase their processing ability and precision in a narrow category, but often at the expense of processing outside that category.

perceptual reasoning index A subcomponent of the WISC-IV that uses pictures and other visual materials and largely avoids using language to assess intelligence. It includes items testing the ability to (1) complete missing details in pictures, (2) arrange pictures to form a reasonable sequence of events, and (3) use blocks to re-create abstract designs.

perceptual-motor development Development that proceeds through an integration of action with perceptual feedback. While normally discussed with respect to vision, it can also apply to other modalities.

permissive parent A parent who adopts a style of child rearing that is warm but sets few if any guidelines for the child's behavior.

personal moral situation A moral situation in which individuals are depicted in personal ways that invoke strong, immediate judgments that often bypass more abstract and reflective moral reasoning.

pervasive developmental disorder A disorder in which there is a broad spectrum of problems usually associated with delays in socialization and communication. The term is often used to describe individuals with symptoms similar to those found in autism.

phenotype The physical manifestation of a gene sequence, either with respect to one trait or with respect to the entire organism, including its anatomical structures, biochemical processes, and behaviors.

phobia An extreme, often irrational fear of a specific thing or situation.

phoneme The smallest unit of a language that makes a difference in word or morpheme meaning.

phonics approach An approach to reading that emphasizes the sounds of letters and letter patterns and how they can be combined into larger units.

phonological awareness An understanding of the sound units and sequences in spoken language.

phonology The sound patterns of a language and the rules that govern them.

pictorial cue A cue to the perception of depth that arises from information in two-dimensional pictures.

place error Another name for the A-not-B error.

placenta The organ that is attached to the mother's uterus and connected to the developing fetus by the umbilical cord and through which nutrients and oxygen are transferred from the mother and wastes and carbon dioxide from the fetus.

plasticity Flexible abilities that enable a developing organism to be responsive to changing environmental contingencies.

platoon school A model of education promoted by William Wirt early in the twentieth century that stressed efficiency and envisioned modeling student instruction in a manner analogous to the new technology of assembly lines.

pleiotropic Referring to a single gene that affects many traits.

polygenic Referring to a trait that is affected by many genes at the same time.

popular child When sociometric status is measured, a child who is nominated as being liked by most children and disliked by few children, often as a result of both appealing physical attributes and social skills. Sociometric popularity contrasts with perceived popularity, which may be more related to perceived dominance and power than to kindness and trustworthiness.

positivity bias A tendency for older adults to process information in a more positive manner than younger adults.

poverty of the stimulus argument The idea that the linguistic information that a child hears is so impoverished that, on its own, it is inadequate to explain the ability to learn a language.

pragmatics The ways in which language is used to effect successful communication in social contexts, conveying intended meanings such as inferred goals and motivations.

preferential looking method A method to determine whether a subject can detect a difference between two types of displays, implied when the subject looks at one display more than the other.

prefrontal cortex The front-most region of the frontal lobes, which is often heavily involved in many aspects of memory, including memory storage and retrieval and the use of various memory strategies.

prelinguistic vocalization Any of a number of sounds made by the infant prior to the clear use of language. Vocalizations include babbling but can also include other earlier sounds, such as cooing and squealing.

preoperational period A stage of cognitive development occurring after the sensorimotor period, at roughly 2 to 7 years. In this stage, children are able to represent the world in symbolic terms, but have difficulty thinking nonegocentrically or considering different dimensions of situations and the relations between them because they are missing mental operators.

prepared Having a tendency to associate a class of responses more easily with one class of stimuli than with another without having prior experience with those stimuli.

prereaching Mostly failed attempts to touch objects by very young infants.

preterm infant An infant born 3 or more weeks early; also known as a premature infant.

primacy effect When memorizing a list of items, the tendency to better recall items near the beginning of the list relative to items in the middle.

primary circular reaction The discovery by chance of new ways of acting on one's own body.

primitive streak A ridge of tissue that emerges early in prenatal development and that forms the basis for an environment that induces changes in cells that pass through the streak to become the mesoderm and endoderm.

principles and parameters approach An approach advocated by Noam Chomsky that says that there are a common set of principles that govern the internal structure of all languages and that, early in life, the child's mind contains a large number of possible linguistic forms or alternative parameters that will later become fixed based on the specific language the child learns.

private self A sense that we have experiences that no one else has, such as dreams, points of view, and thoughts.

proactive aggression Aggression that is engaged in against another person without provocation and usually as a way of achieving a goal, such as obtaining material goods or causing intimidation or suffering in a victim.

procedural memory Memory of how to perform certain actions or procedures; "knowing how" memory. Many procedural memories, but not all, are also implicit memories.

processing speed index A subcomponent of the WISC-IV that measures how quickly a child seems to process information in tasks ranging from time spent searching for a target shape among a much larger set of shapes to tasks identifying all instances of a target image—for example, an animal or a specific number—in a very cluttered field of diverse objects.

production deficit An apparent inability to spontaneously use a strategy that would clearly improve performance on a memory task.

prosocial behavior Behavior that benefits other individuals, groups, or the society as a whole, often at a cost to the person who engages in the behavior.

prosody The acoustic properties of speech, such as intonation, rhythm, and pitch.

prospective memory Remembering to do a task or attain a goal in the future.

psychobiomarker A biological feature, such as telomere length, that can be used as an index or marker of a person's psychological state, indicating, for example, a recent history of high levels of stress.

psychometric approach An approach to the study of intelligence based on the scores on standardized tests administered to large groups of people. These tests tend to focus on analytical forms of intelligence.

psychopathy A disorder in which a person seems to lack empathy or a moral sense to guide his or her actions and manipulates victims through lies, deception, and distortions.

psychosexual development A series of stages of development proposed by Freud and related to drives, instincts, and sources of pleasure, with a particular focus on sexual desire.

psychosis A loss of contact with reality, as often shown by hallucinations and delusions in a person with schizophrenia.

psychosocial conflict According to Erik Erikson, a conflict that characterizes each stage of psychosocial development and that must be successfully resolved to form a good foundation for the next stage and its challenges.

qualitative change A stagelike form of developmental change in which a new kind of structure or process emerges that was not present before the change.

quantitative change A developmental change in which the same structures and processes remain but change in magnitude—for example, an incremental expansion to a mental process rather than a totally new kind of mental process.

radial glial cell A special glial cell that acts as a guide for the migration of nerve cells in areas such as the cerebral cortex.

reactive aggression Aggression that is engaged in as retaliation for aggression against oneself.

recasting Repeating back a child's utterance to him or her, but with expansions of the sentence into a larger, grammatically correct form, or repeating an ungrammatical sentence back in grammatical form.

recency effect When memorizing a list of items, the tendency to better recall items near the end of the list relative to items in the middle.

recessive Referring to an allele that is not expressed in the phenotype when paired with a dominant allele; if the alleles in the pair are recessive homozygous, however, their properties will be expressed.

referential communications task A task in which a speaker tries to communicate to a listener, who cannot see the speaker, a series of operations that involve reference to a set of materials that both the speaker and the listener have in front of them.

reflex An innate response that occurs automatically to a particular form of stimulation.

regulatory cascade A series of interactions consisting of sets of genes that turn other genes on or off. When one gene can turn on other genes that turn on still other genes, a cascade is said to occur.

rehearsal A memory strategy consisting of repeating the information to be remembered.

rejected child A child who is nominated as being disliked by most children and liked by few children on an assessment of sociometric status. Rejected children often interpret ambiguous situations in a hostile way.

relational aggression Aggression that is intended to damage a social relationship between a victim and other individuals. Gossip, rumor, and ridicule are often the weapons used to damage another person's reputation and that person's relationship with others.

reliability The capability of a research design to achieve the same results when repeated with the same kinds of participants.

replicability The ability for others to easily reproduce a study and find the same results.

resilience The ability of some children to have very positive behavioral and psychological outcomes, despite growing up in an environment that normally is associated with a high incidence of behavioral and psychological problems.

resistant attachment *See* insecure/resistant attachment.

resource theory The idea that the more children there are in a family, the fewer resources there are for each child.

response modification A form of emotional regulation that involves managing an emotional reaction by directly influencing the response itself or engaging in an activity that indirectly reduces anxiety or increases arousal.

retrieval The process of finding a memory in storage and bringing it to mind for use, usually in a conscious manner.

reversibility A mental operation, according to Piaget, that emerges in the concrete operational period and that enables the child to realize that certain transformations on the physical world are reversible.

riddle of reference The dilemma of knowing whether a word refers to a whole object, a set of its parts, or an event or action associated with the object.

romantic relationship A mutually recognized voluntary interaction that is seen as more intense than other relationships and that is also distinguished by displays of affection, either with actual sexual behavior or the anticipation of such behavior occurring.

rooting reflex A reflex found in newborns in which a gentle touch on the cheek results in movement of the face so as to bring the mouth around the touching object.

rumination A form of cognition in which the individual dwells on negative events in ways that may help maintain a depressive state.

sampling bias A problem in research in which participants are selected in a nonrandom manner that suggests a relationship that might not really be present in a truly random sample.

Sapir-Whorf hypothesis The idea that specific languages powerfully mold thought, affecting how individuals perceive and understand the world.

scaffolding A process through which adults and older children structure the young child's environment and social milieu in a manner that enables the child to move to new levels of cognitive achievement.

scheme A complex of mental structures, processes, and actions that are used to interact with the environment.

schizophrenia A cluster of disorders in which there may be hallucinations and delusions, disorganized thoughts, chaotic speech and behavior, and difficulties responding and communicating with others.

scientific reasoning The ability to develop and test hypotheses about some aspect of the world and then efficiently test those hypotheses with relevant data.

secondary circular reaction A scheme that is applied directly to external objects (beyond the infant's own body) and modified accordingly.

secure attachment An attachment style in which infants show some distress when the mother leaves, but not an excessive amount, and show positive affect when she returns. They also show substantial exploratory behavior in the presence of the mother, using her as a secure base.

secure base The role that a caregiver may play with respect to a securely attached infant, who uses the caregiver as a base from which to explore.

security motivational system A system that has been selected for by evolution and that is meant to increase vigilance for future threats to one's well-being, including clues to predators, toxins, and harmful changes in normal routines.

self-concept A conscious sense of the self that involves both facts about the self and evaluative beliefs about the self.

self-conscious emotion An emotion that requires some degree of self-awareness and an evaluation of the self as distinct from others and in relation to others.

self-determination A sense of having a choice in decisions about our life and daily activities, of feeling that we have had an important role in determining our behaviors.

self-efficacy Our beliefs about our ability to achieve certain goals, often tied to a particular set of circumstances.

self-esteem The extent to which we value our own worth and the emotions that accompany such an assessment.

self-regulation The ability to regulate our own emotional states and reactions to situations and others. This may also include the ability to understand and evaluate our emotional states and the consequences of those states for ourselves and others.

semantic development The process of learning word meanings and their interrelationships by linking words to concepts and then applying those concepts to objects.

semantic memory Memory for episode-independent facts, such as the capital of a country or the meanings of words; a component of declarative memory.

semantics The ways in which words and the relations between them yield meaning.

sense of self A composite of the various ways an individual thinks about himself and has distinct kinds of self-awareness.

sensitive period A period in development when learning a particular kind of information is much easier. Before or after such a period, learning is more difficult.

sensorimotor period According to Piaget, a period of development from birth to 2 years of age, when infants largely understand the world in terms of the way they perceive and act on it and understand objects primarily as embedded parts of perceptual and motor activities.

sensory memory A brief memory for sensory information, such as visual images, sounds, odors, tastes, and touch.

separation anxiety *See* separation distress.

separation distress The distress felt by an infant when a specific individual with whom the infant has a specific bond leaves. The infant wants that particular person—not just any social partner—to come back. Also known as separation anxiety.

serial position curve A record of recall of a list of serially presented items, showing different rates of recall as a function of where the items appear in the list. In adults, the curve usually has a U shape, with greater recall near the beginning and the end of the list.

seriation The ability to order objects according to a shared property, such as length. This ability is often facilitated by transitive reasoning.

sexual diffentiation A process in which differences between females and males are initiated by the X and Y sex chromosomes, which trigger and regulate sex hormones that affect male or female characteristics. These differences appear in major anatomical structures, in physiological systems, and in the brain.

shape bias A putative constraint on word meaning in which labels, when applied to objects, are assumed to apply to other objects of the same shape.

shaping The gradual modification of a behavior through operant conditioning, by gradually rewarding behaviors as they come closer and closer to resembling a desired behavior.

sibling differentiation A phenomenon in which siblings strive to occupy contrasting social and skill niches as a way of developing their own distinctive identities in a family. This is in contrast to the case where younger siblings imitate older ones.

simple reaction time The time it takes to engage in a motor response for a stimulus, such as pressing a key whenever a particular stimulus appears.

situation modification A method of emotional regulation that involves changing the circumstances that bring about an emotional reaction.

situation selection A method of emotional regulation that involves choosing one's circumstances based, in part, on the kind of emotional reaction they elicit.

situational factor A factor that arises from external circumstances and influences behavior.

social aggression A kind of aggression that includes such behaviors as malicious teasing, social exclusion from a group, and humiliation.

social anxiety disorder A disorder in which the individual feels intense anxiety in social situations, often concerning how he or she is viewed by others.

social comparison The act of comparing ourselves to another as a way of calibrating our standing in a group or relative to another group. Such comparisons emerge strongly in the elementary school years.

social convention A rule of human interaction that is jointly decided upon as a means of achieving some sort of coordinated activity in which both parties will benefit. Such rules are usually arbitrary, such as driving on a particular side of the road, but they must be honored by everyone once they are established.

social information processing An approach to encoding, interpreting, and responding to social cues that is often used to explain peer group acceptance or rejection.

social intelligence The ability to manage our interactions with others.

social intuitionist model A model of moral judgment in which perceived violations of norms and rights automatically trigger emotions like anger or contempt without consideration of abstract moral principles.

social learning theory The idea that people tend to copy behavior modeled by others, especially those they like and respect; also called modeling theory.

social referencing The use of the emotional and social states of others as information on how to interpret a situation.

sociometric status A person's social standing in a group, often computed from a combination of ratings of how much the person is liked and disliked by peers in that group.

source monitoring The ability to keep track of the sources of our memories, such as whether we experienced them directly, learned them from someone else, or acquired them through a dream.

specific bond A bond to a particular individual, usually formed at about 6 to 7 months. Also called specific attachment.

specific language impairment (SLI) A language impairment in which there are highly specific problems with particular syntactic structures, such as noun-verb agreement and the use of articles and prepositions.

sperm cell The male gamete that combines with a female gamete (egg cell) during fertilization.

stages of development Relatively discontinuous changes in thinking and behaving, resulting in new kinds of accomplishments and patterns of thought that were not present before that stage.

standard deviation An indication of how much variation there is from a mean score—that is, how widely scores are distributed around the mean. One standard deviation encompasses roughly 68 percent of all scores, two standard deviations encompasses roughly 95 percent of all scores, and three standard deviations encompasses roughly 99.7 percent of all scores.

statistical learning Learning based on the probability of events co-occurring or occurring in certain orders.

stem cell An undifferentiated cell that can become a cell of any type.

stepping reflex A newborn reflex of engaging in repetitive stepping motion when held upright.

stereopsis The fusion of an image that is seen with both eyes, a fusion that uses binocular disparity to compute depth and give a sense of three-dimensionality.

stereotype threat The perception that an activity, usually some sort of performance, such as taking a test, is governed by a negative stereotype about the group to which one belongs. Fear of confirming that stereotype then reduces task performance.

still face An impassive, straight face shown by a caregiver in the still-face task, in which the caregiver abruptly stops interacting with an infant and breaks the normal cycle of social interaction by showing unresponsive facial expressions.

storage The process of preserving information in memory over time.

Strange Situation A series of laboratory episodes developed by Mary Ainsworth and used to measure the kind of attachment a child shows to a parent. The method examines an infant's reactions to unusual, mildly threatening situations in the presence of a parent and when the parent has left the room, as well as how the child responds when the parent returns.

successful aging A pattern of aging that reflects the adoption of strategies and behaviors that optimally adapt an older person's changing skills and abilities to her daily activities.

superego One of three components of mind described by Freud; it represents the emergence of a conscience, an internal sense of right and wrong.

synapse The gap between two nerve cells where a signal can be transmitted by a neurotransmitter.

synaptic pruning The process by which extra synaptic connections are reduced in normal development.

synaptogenesis The process by which new synapses are created.

syntax The ordering relations in a language that yield what is normally thought of as a grammar.

tabula rasa A "blank writing tablet" or "blank slate," used as a metaphor by empiricists to describe the newborn's mind as completely malleable by experience; originally used in a Latin translation of Aristotle, but attributed to John Locke, who actually used the metaphor "white paper."

telegraphic speech Speech by young children that is severely truncated by dropping out nonessential elements such as articles, prepositions, and pronouns.

telomerase An enzyme that re-extends telomeres and which may be used by cancer cells to keep dividing in ways that exceed the Hayflick limit.

telomere An ending on a chromosome that is thought to shorten with each cell division and to be the reason for the Hayflick limit.

temperament Early emerging behavioral characteristics that distinguish one infant or young child from another, typically understood as precursors to later emerging personality traits.

temporal lobe A lobe in the cerebral cortex with structures that process auditory information and other aspects of language meaning and that support crucial components of memory.

teratogen An internal or external hazardous environmental factor that can potentially cause problems during the prenatal period. Teratogens include drugs, diseases, malnutrition, and environmental toxins.

tertiary circular reaction A scheme used intentionally by infants to actively explore the world. With such reactions, infants start to recognize objects as entities in their own right, independent of specific schemes.

theory of mind A well-developed set of untaught, intuitive beliefs about others' mental states and processes and an understanding of how to use those beliefs to infer others' goals and explain their actions.

theory of mind module (TOMM) A specialized, autonomous system dedicated to processing the beliefs and mental state processes in others.

trait-based reasoning Thinking about an individual's qualities and behaviors in ways that focus on specific traits. (*Compare* evaluative reasoning.)

transitive reasoning A way of reasoning about known relationships to make logical inferences about other unknown or less direct relations (for example, if A is taller than B, and B is taller than C, then A must be taller than C). Some theories have argued that young children are unable to reason transitively.

trisomy 21 A defect resulting from an error in meiosis that results in three chromosomes for chromosome 21 and leads to Down syndrome.

unconditioned response (UCR) A response that is normally associated with a stimulus without the need of associative learning.

unconditioned stimulus (UCS) A stimulus that normally elicits an unconditioned response.

underextension A phenomenon in semantic development in which the child uses a word to apply to a smaller set of entities than is normal in adult usage.

unipolar depression An affective disorder in which a severe and sustained drop in affect is often accompanied by agitation, feelings of sadness and worthlessness, insomnia, and loss of appetite.

universal constraints Limitations on the sets of language rules that are cognitively natural, resulting in consistent patterns of linguistic structure seen in all languages and thereby aiding in language acquisition.

U-shaped developmental curve A developmental pattern in which an early, rudimentary ability or capacity initially declines with increasing age and then increases, becoming more sophisticated than it was at the start. This pattern is associated with the replacement of an early system with a later-emerging, more mature one.

utilization deficit An inability to benefit from a memory strategy when it is first used.

validity The capability of a research design to measure what was intended to be measured.

verbal comprehension index A subcomponent of the WISC-IV that measures both comprehension of language-based materials and the ability to solve problems posed in words. It includes questions designed to measure vocabulary, general knowledge about the world, and some questions that require abstract reasoning about similarities.

video deficit The relative inability of younger children to learn as effectively from viewing videos as from watching live demonstrations.

visual acuity Sharpness of visual perception based on the ability to see the contrasts in the world that represent lines, shapes, and shadows.

visual cliff An apparatus for assessing depth perception in infants. It consists of a large, transparent and nonreflective pane of glass with two similar patterned displays below it. One-half of the glass pane has a pattern directly beneath it, so that the surface appears solid, and the other half of the glass pane has the same pattern roughly 3 feet below, giving the impression of a sudden drop-off. If the infant perceives depth, she will be afraid to crawl over the half of the glass pane that appears to have a drop-off.

visual flow fields The streaming visual patterns made by objects and terrain over time as they flow by an observer who is either moving or is having the environment move about her.

visually evoked potential (VEP) method A method of measuring at what point of resolution the changing patterns that an infant is watching on a screen no longer cause corresponding changes in his brain's electrical activity.

vitalism The belief that living things are imbued with a vital force that is the cause behind growth, movement, and possibly other biological activities.

whole language approach An approach to reading that emphasizes reading in the context of stories, narratives, and even pictorial support.

whole-object bias A bias to assume that labels refer to whole objects rather than their parts, their colors, or other properties.

Williams syndrome A genetic disorder leading to an elfin appearance and below-average intelligence but in which individuals seem to have intact language skills while having considerable difficulties in many other areas of cognition.

within-subjects design A research design in which the same participants are assessed in different experimental conditions.

working memory A form of memory in which incoming information is attended to and processed in a preliminary or limited way before it either decays or is further processed into long-term memory; also referred to as short-term memory.

working memory index A subcomponent of the WISC-IV that assesses performance on tasks that draw on working memory. It includes doing simple arithmetic tasks and remembering strings of digits either backwards or forwards.

zone of proximal development A level of cognitive attainment that is the next possible achievement by a child, often made possible through adult guidance.

zygote A fertilized cell formed at conception from the merging of the father's sperm and the mother's egg.

Subject Index

Page numbers in italics refer to figures. Page numbers followed by an italicized *t* refer to tables.

ABO gene for blood type: alleles for, 37
Abraham, Nathaniel, 457, *457*
absolutism, 372
abstraction: categorization in infancy and, 174
abstract rules: learning, 271, *271*
abstract-to-concrete shift: in mastery of biological concepts, documenting, 332
abused children: emotion perception and, 240–41, *241*
academic achievement: self-esteem and, 478, 479; social network effects and, 558; summer vacation time and decline in, 412; television watching and, 564
academic success: predicting, intelligence tests and, 389
academic television programs: positive effects of, 562
accents (linguistic): biases related to, 577
accommodation, 147, 148, *148,* 150, 311
acetylcholine: orienting and, 360
acquired taste, *108*
action potential, 59, 60
action(s), 142; active *vs.* passive visual experience and, *126,* 126–27, *127,* 128; behaviorism and, 139; before birth, 116; development of, 8, *9*; at a distance, and social contingency, *176,* 176–77; imprinting, critical periods and, 135–36; inferring from emotions, 238, *238*; mirror neurons, early imitation and, 134; perception and, 122–31, 143; specific, learning to engage in, 131–35, 143–44
active learning, 413
active *vs.* passive experience: in Held and Hein study, *126,* 126–27, *127*
activity level, 248
acuity: perceiving differences in brightness and, *79*–83
adaptation, 147
addition, 376; infants and simple form of, 167–68, *168*; learning strategies for, 376–77; monkeys and notion of, 168
adenine: DNA double helix and, 36, *36*
ADHD. *see* attention deficit hyperactivity disorder (ADHD)
adolescence, 7–8; anorexia during, 598, 599, *602*; bulimia during, 602, I602; bullying in, 550; dating and romantic relationships during, *552,* 552–53; depression in, rise of, *604*; friendship jealousy in, 547; peer interactions and, 546; risk taking in, 64, 645; schizophrenia in, 615; self-esteem in, 475, 476*t*; social network effects and obesity in, 558; unipolar depression during, 604
adolescents, 8; changes in reward and control circuits in, *67*; diagnosing psychopathy in, 611; eating disorders in girls, 598; friendships among, 547–48; rumination and depression in, 607
adopted children: wide variation in outcomes for, 218
adoptions: by same-sex parents, 530, 531
adoption studies: on anxiety disorders, 595; on criminality, 453; temperament and, 254
adult development: understanding stages of, 652
adulthood: cognitive changes in, 657–58; physical and physiological changes in, 630–31, 634–35, 657
adult relationship styles: infant attachment styles and links to, 210
adults: changes in reward and control circuits in, *67*
adverse childhoods: creative genius and, 421
advertising: stereotyping in, 568; television, children and, 560
aerobic exercise: cognitive aging and, 640, *640*
affection: human attachment and, 192
affective blunting: schizophrenia and, 616
affective factor: in psychopathy, decreased brain activation and, *614*
affiliation levels, 544–59, 582; changing nature of social interactions, 545–46; developing relationships, 546–53; developmental changes in social affiliations, 559*t*; developmental patterns in, 558; social groups, 553–58; social network effects, 558–59
affluence: television and norms of, 569
affordances: for action, properties of objects/surfaces and, 129–30
African-American children: self-esteem in, 478
African-American culture: cultural teachings of U.S. schools *vs.,* 411–12
African-American families: single-parenting and, 530
African-American mothers: mean age for first births and, 527, *527*
African-American parents: parenting interventions by, 510
African Americans: awareness of stereotypes, intellectual abilities and, 406; divorce rates among, 532; Flynn effect and, 406; IQ scores and, 402, 403; racial and ethnic occupational stereotypes and, 578, *579*; reframing tasks and reducing stereotype threat for, 405; "social" category of, intelligence test scores and, 403; sociocultural stereotypes and, 404; stereotype threat and, 404–5
African descent: genetic diversity among people of, 403, *404*
age: anorexia nervosa and, 598, 599, *602*; antisocial behavior and, 448–49; bulimia nervosa and, 602, *602*; children's memory capacity and, 413; collision rates by, *651*; computer use or Interest use by, 572, *572*; correlates of intelligence test scores with, 390; delay of gratification and, *477*, 479–80; developmental periods based on, 7; drawing skills and, 380, *380*; gender stereotype rigidity and, 577, *577*; heritability of height and, 400; heritability of intelligence and, 398, *398*; illusions of knowing and, 371; information integration theory and, 313, *313,* 436; intelligence quotient and, 387–88; language acquisition and, 281–84, 301; media portrayal of, 653, *653*; motherhood and, *526,* 526–27; optimism and, *496,* 496–97; presidency of U.S. and limits for, 630, *630*; romantic relationships and, 552, *552*; self-efficacy and, 477;

age (*continued*)
self-esteem and, 475, 476*t*; serial position curves and, 349, *349*; television watching relative to, *561,* 561–62; traffic fatalities and, 645, *645*. *see also* aging
ageism: cultural variation in stereotypes and, *655,* 655–56; stereotypes and, *654,* 654–55
agents: order and, 182, *182,* 183
aggression, 448, 557; bullying patterns of, 550; child abuse and, 537; culture of honor and, *574,* 574–75; cyberbullying, 573–74; dominance hierarchies and, 553; between enemies, 551–52; physical punishment and, 459; proactive, 550; reactive, 550; relational, 547, 551, *552*; serotonin levels and, 221; social, 454; verbal, 547; violent cartoon programs and, 23, 24; violent television programming and, 564–66, 565*t*; violent video games and, 571–72
aggressive thoughts: unwanted, OCD and, *595*, 596
aging: circadian rhythms and, *641,* 641–42; cognitive, daily activities and, 639–41; consistent cognitive improvement with, 637, *637*; fluid *vs.* crystallized intelligence and, *636,* 636–37; memory and, 635–37; pathological, 630, 642; prospective memory and, 638; reaction time and speed of processing with, 635; reasons for, 632–33; sex ratios and, *633*; successful, 630, 631, 634, 642; variations in patterns of, 631. *see also* ageism; aging
agreeableness, 643, 644; group changes in, *648*
AIDS: OCD and excessive worries about, *595*, 596–97
Ainsworth, Mary, 188, 204, 210, 211; Strange Situation and, 202; study of attachment from ethological approach by, *192,* 192–94
airplane piloting: video games skills and, 570
Aka fathers (Africa), 204
Alaska Native mothers: mean age for first birth and, *527*
alcohol consumption: during pregnancy, intelligence test scores and, 407; pregnancy and, 7, 54, *56,* 107; preterm births and, 48; social network effects and, 558
alerting: attention and, 359, 360–61, 363
alleles, 37, 42
allocentric representation: spatial relations and, 169, 170, 171
alphabet: learning, 372
alphabetic principle, 373
ALS. *see* amyotrophic lateral sclerosis (ALS)
alternative meanings test: creativity measured with, 417
alternative uses strategy: creativity measured with, 417
altruism, 5, 443; reciprocal, in primates, *429*
altruistic behavior, 452, *452*
altruistic helping: development of, 451–52
Alzheimer's disease, 634, 635, 642; voting rights and, 650–51
amenorrhea: anorexia nervosa and, 599, 599*t*
American children: early childhood amnesia and, 355–56
American Indian children: early biological thought in, 337
American Sign Language (ASL): acquiring after the critical period, 283; chimps and, 288–8*9*
Amish people, 404
amnesia: early childhood, 355–56; infantile, 353
amygdala: basic emotions and, 233; positivity effect and, 646; psychopathy in adults and deficit in, 612–13, *614*; risk taking during adolescence and, 65; temperament, genetic pathways and, 248
amyotrophic lateral sclerosis (ALS), 66
analogical reasoning, 366–68, 382; defined, 366; in face of perceptual distractors, 368, *368*; in preschoolers, 367, *367*
analogies: in psychometric tests, *388*
analytical abilities: successful intelligence and, 394
analytical intelligence, 395; Head Start and, 409
anatomical development, 44–50, 52–55; adverse influences on embryo and fetus, 53–55; diversity out of uniformity, 49–50; embryonic period, 44–47; preterm births, 47–48; progression in, 49; sexual differentiation, 52–53
androstenedione: qualitative changes during puberty and, *11*
anger, 6, 70, 231, 249, 430; facial expression in infant, *232*; goal and action related to, 230, 230*t*
animal behavior: environment and, 141–42
animals: biological beliefs about, 327; children and understanding of insides of, 332, *332*; psychopathy and cruelty to, 614
animated objects: categorization in infancy and, 175, *175*
animates: perceivable properties distinguishing inanimates from, 175–76, 175*t*
animism: Piaget's interpretations about, 330, 331
anorexia nervosa, 598–602, 626; age of onset in, *602*; cognitive distortions in, 600, *600*; cross-cultural differences in, 599–600; diagnostic features of, 598–99, 599*t*; family therapies and, 622; genetic and environmental causal factors in, 601–2; incidence of, 599–600; introduction of television into rural Fiji and, 569, *569*; in young adults, *599*
anorexic families: traits in, 601–2
A-not-B error: examining, 155–57; Piaget's interpretation of, 153, *153*; pragmatic factors and, 155–56, *156*; spatial knowledge in infants and, 170
antidepressants: prescribed for preschoolers, 623; rise of use in children, 622, *622*, 624
antipsychotic drugs, 624
antisocial acts: violent television programming and, 564
antisocial behavior, 448–49, 456, 464, 514; conduct disorder and, 454; genetics, psychopathy and, 613; modeling theory and, *461,* 461–62; self-regulation and, 452–53
antisocial factor: in psychopathy, decreased brain activation and, *614*
antisocial interactions, 545
Antisocial Process Screening Device (APSD), 613, *613*
anxiety, 6, 70; child abuse and, 537; in children in orphanages and foster home care, 218; rejected children and, 557
anxiety disorders, 587, 592–98, 625–26; anorexia nervosa and, 599; biological factors in, 595; causal factors in, 593–95; cognitive and attentional biases contributing to, 594, *594*; cognitive-behavioral therapy in treatment of, 621; cognitive factors in, 594–95; earliest signs of, 593; incidence of, 592–93; obsessive-compulsive disorder, 595–98; spectrum of problems tied to, 592
anxious attachment: Type C infants and, 202, 203
anxious temperaments: *Ce* gene and, 248
aphasias, 285
apoptosis, 61; deprivation and, 64
APSD. *see* Antisocial Process Screening Device (APSD)
aptitude-treatment interactions: learning and, 416–17
Arabic language: learning to read in, 307
arbitrary rules: children's sense of moral laws *vs.,* 435
Aristotle, 64
arithmetic, 376; complex web of knowledge tied to, 169; infants and simple form of, 167–68; intuitive skills in, 324
Aronson, Joel, 404, 405
arousal levels: positive emotionality and, 454
ASD. *see* autism spectrum disorder (ASD)
Asian-American girls: stereotype threat, math tasks and, 405, *405*

Asian-American mothers: mean age for first birth and, *527*
Asian Americans: awareness of stereotypes, intellectual abilities and, 406; divorce rates among, 532; IQ scores and, 402
Asian cultures: self-regulation in, 482, *482*
ASL. *see* American Sign Language (ASL)
Asperger's syndrome, 588, 589, 590; gender and, 590; genetic influences and, 591; genotypes for social skills and, 206; theory of mind and, 483
assimilation, 147, 148, *148,* 311
associative view of strategy development, 377
asthma: ADHD and, 364
astigmatism, *82*
athletic performance: popularity and, 555
attachment, 188; components of, 194–98; contingent responding and, 199; dependency *vs.,* 194; in different species, 192, *193*; ethological approach to, 192–94, 223; evolutionary function of, 193; joint attention, gaze following and, *200,* 200–201; learning theory views of, 191–92; origins of, 189; peer relations and, 544; psychoanalytic approaches to, 190–91; serotonin and, 221; social referencing and, 200; still-face studies on, 199; underpinnings of, 224
attachment complex, 194
attachment-in-the-making phase, 193
attachment studies: father's role and, 204–5, *205,* 206; mothers' role and, 204, 205, 206
attachment styles: adult relationship styles and, 210; causes of, 203–8; children's social interactions and, 208–10; commonalities in, 223; consequences of, 208–10; cross-cultural differences in, 210–11, 211*t,* 214; day care and, *212,* 212–13; defined, 201; developmental psychology and basis of, 202; individual differences in, 201–11, 214, 224–25; interaction of parent effects and child effects, 208; internal working models and, 208, 209, *209*; Strange Situation and study of, 202–3, *202. see also* social deprivation
attachment theory: cycle of abuse and, 537
attention, 358–66, 380, 382; as active exploratory system, 359; alerting and, 360–61; components of, 359–63; developmental disorders in, 363–66; executive functioning and, 361–63; neuroscience of, 365; orienting and, 360
attentional biases: in anxious children, 594, *594*
attentional deployment: emotional regulation and, 238, 239, 240, *242,* 245
attentional development studies, 362–63
attentional networks: in brain, *362*
attentional schemas, 359
attentional systems: temperament and, 250
attention-deficit/hyperactivity disorder (ADHD): arousal levels and, 454; biological bases of, 365–66; diagnosis of bipolar disorder as distinct from, 609; drug treatment for, 622, 624; first published description of, 363– 364, *364*; misdiagnosis of, 366; prevalence of, 364; symptoms, diagnosis and potential precursors of, 364
attraction effect, 639
attractiveness. *see* physical attractiveness
attribution: motivation, creativity, and, 497–99
attributions: making about ourselves and others, 493–99, 501
attribution theory, 494
audition, aging and, 634
auditory cortex: cochlear implants and, 102
auditory cues: recognizing emotions in others and, 236
auditory processing: cochlear implants and critical periods for, 102
auditory-visual intermodal perception: studies of, 110, 111, *112*
Auschwitz: children behind barbed wire at concentration camp in, *216*
Australian brush turkeys: environmental niches of, 36
Australian children: cosmological beliefs and, 336
authoritarian parents, 506, 507; characteristics of, 507; effects of, on children's traits and behaviors, 508*t*; interventions designed for, 510; psychological control by, 508; stress and, 509
authoritative parents, 506; behavioral control by, 508; characteristics of, 507–8; effects of, on children's traits and behaviors, 508*t*; higher socioeconomic status and, 509
authority/respect moral module, 443*t,* 444
autism, 587, 625; causal factors of, 590–92; diagnosis of, 589; false-belief tasks and children with, 489–90; features of, 588–89; fetal testosterone and subsequent incidence of, 590, *590*; incidence of, 589–90; poor language skills and, 491–92; theory of mind and, 483; visual fixations by toddlers with and without, 588, *588*
autism spectrum disorder (ASD), 588; DSM-V and category for, 590
autistic disorder, 590
autobiographical memories, 348; development of, *358*; long-term, emergence of, 356–58; maternal reminiscing and, 357, *357*; narrative skills and, 358*t*
autobiographical self, 500
autoimmune disorders: autism and, 592
automobile insurance rates: for young adults, 645
autonomous stage: in Piaget's stages of moral reasoning, 432*t,* 434
autonomy: as moral value, 442
autonomy *vs.* shame/doubt: in Erikson's stages of psychosocial development, 649, 649*t*
average babies: in New York Longitudinal Study, 249
average children, 554
avoidant attachments, 211
axons, 59, *59*
axon terminals, *59*

babbling, 264; behaviorist approach to, 269
babies, 47. *see also* infants; newborns
baby schema: Lorenz on, 197; variations in, *198*
baby sib studies, 589
"baby talk," 101
baby videos, 562
Baillargeon, Renee, 158, 161, 162
balance: visual flow fields and, 128–29, *129*
Bandura, Albert: Bobo doll study of, 461, *461*; self-efficacy theory of, 476, 477
Barney & Friends (television program), 563
barn owls: effects of visual distortion on sound localization in, 103, *103*
basal ganglia, 57, *57,* 58
base pairs: DNA, 36, *36*
basic emotions, 230–33; facial expressions of, in infants, *232*
basic level of categorization, *316,* 316–17
Baumrind, Diana: parenting styles proposed by, 506
Bayesian learning model, 272
Bayes's rule: language learning and, 272
Bayley, Nancy, 396
Bayley Scales of Infant Development, 396
beacons: spatial knowledge in infants and, 170, 171
beard growth: "nature/nurture" debate and, 12
Beautiful Mind, A (film), 614
Beck, Aaron, 606, 620
Beethoven, 421
behavior: attachment and, 192; emerging explanations of, 493–96
behavioral control, 508
behavioral genetic approach: cycle of abuse and, 538
behavioral genetics, 35, 67–70, 73; behavioral genomics, 68–70; heritability, 67–68
behavioral genomics, 68–70
behavioral tendencies: intrinsic, 16, *16*
behavioral therapies: in treatment of childhood pathologies, 619–20
behaviorism, 269; defined, 139; platoon school movement and, 411

behaviorist approaches: to development, 19, *20,* 31; to language acquisition, 269
behavior modification, 19
belief attribution: goals and, 177–80, 182–83
belief-induction trial, 178, *179*
bell curve: intelligence test scores and, 389, *389*
Berkeley, George, 15, *15,* 87, 88, 92, 123
Berkeley Free Speech Movement: moral judgments and moral actions in, 444–45, *445*
Berko-Gleason, Jean: plurals study of, 266, *266*
Berlin Wall: fall of, attachment patterns in families after, 210
Bernstein, Nikolai, 120, 121
between-subjects design, 30, 32
bias: shape, 275; whole-object, 275, *276,* 278
Big Five personality traits, 643, 644
bilateral symmetry, 44
bilingualism: cognitive effects of, 296–97
Binet, Alfred, 146, 387, 397
binge eating, 598, 602
binocular cues, 91; to depth, 86, *87,* 87–88; emergence of, *91*
binocular disparity, 87
binocular parallax, 87, *87,* 88
binocular vision, 307; nature/nurture question and, 13
biological explanatory system: basis of, 329
biological factors: in anxiety disorders, 595; intelligence test scores and, 407; in schizophrenia, 618
biological knowledge: exposure to nature and, 333, *333*
biological properties: attributing, Carey's studies on children and, 330–31, *331*
biological sex: gender identity and, *473,* 473–74
biological system: inputs into, 36–38
biological thought: culture and emergence of, 337; development of, 339; intuitive, universality of, 327–28
biology: in domains of knowledge, 327–34
biology of development, 33–74; anatomical development, 44–50, 52–55, 72–73; basis of development, 35–38, 72; beginnings of development, 41–44, 72; behavioral genetics, 67–70, 73; brain development, 56–65, 67, 73; constraints on development, 38–41
"biopsychological" approaches: to family dynamics, 514
bipolar disorder, 603–4, 607–9; causal factors in, 609; diagnosis of, 609; heritability of, 609; phases in, 603–4, 607; unipolar depression *vs.,* 603*t*
bipotential gonads, *52*
birds: imprinting in, 135–36, *136*
birdsong, 142; development of, imitation theme and, 133, 135; in Japan, imitation of, 133, *135*
birthday party videos: diagnosis of autism and, 589
birth order, 505, 518–20; early childhood amnesia and, 356; intelligence test scores and, 408, *408,* 421, 518–19, *519*; interactionist approach and, 520
births: of first child, median age of parents over the last century, 525, *525*; preterm, 47–48
bisexual romantic patterns, 552
bitter taste, 107; acquired tastes and, *108*; disgust reactions to, 246, *247*; facial response to, *108*
black bile, 248
blastocyst: formation of, 43, *44*; implantation of, *46*
blastula, 71
blended families, 505, *535,* 535–36
Bleuler, Eugen: on "group of schizophrenias," 615
blind children: walking and, 127–28
blocking effects, 140–41
blogs: free speech and, 571
blood, 248
blood types: alleles and, 37
Blues Clues (television program), 562, *562*
Bobo doll study: aggressive behavior modeled in, 461, *461,* 566
bodily/kinesthetic intelligence: creative geniuses and, 420, 420*t*; Gardner's theory of multiple intelligences and, 393, 393*t*
bodily proportions: changing, *123*
body development: genes and, 50
body distortions: in those with anorexia and bulimia, 600, *600*
Bond, Julian: minimum age for presidency and, 630, *630*
bonds: early, development of, 189*t*; Freud's theory of, between infants and parents, 190
bone density: aging and, 631
bonobos: invisible displacements and, 164; joint attention and, *289,* 289–90
bootstrapping, 326
border collie: temperament in, *251*
bottle-feeding, 191
bottle-nosed dolphin: mirror test with, 471, *471*
Bowlby, John, 188; internal working model of, 208; study of attachment from ethological approach by, *192,* 192–94
Boykin, Wade, 411
boys: adolescent romantic relationships and, 552; anorexia nervosa in, 599; anxiety disorders in, 592; athletic performance and popularity in, 555; autism diagnosis for, 590; bulimia in, 602; cyberbullying and, 574; divorce and impact on, 533; eating disorders in, 598; effects of parental socialization on, 516*t*; fetal testosterone and diagnosis of autism-related symptoms in, *590*; friendships and, 547; language-based tasks and, 401; one-child policy in China and ratio of girls to, 523, *523*; parenting styles and effects on, 508*t*; physical aggression between, 551; presocialization toy preferences and, 517–18; qualitative physical changes during puberty and, 10; sex differences in intelligence and parental interactions with, 401; sex-stereotyped toys for, 515; sexual abuse of, 536, 537; stepparents and, 536; of teenage mothers, 527; toy preferences in, 516
Brahman caste, Nepal: social behaviors and, 575
brain: aging and decrease in size of, 631; alerting network and, 360, *362*; basic structure of, *57*; categorical perception of color and, 85; executive functioning network and, 361, *362*; face area of, emergence in, *98*; initial formation of, 46; male and female, biological differences between, 401; maturation of, neuroscience perspectives and, 19; memory and regions of, 345, *345*; number awareness, mathematical skills and, 169; orienting network and, 360, *362*; reaching and changes in, 125; self-regulation and maturation of, 480–81
brain activity: infant, near-infrared spectroscopy and, 21, *21*
brain damage: habituation times in children with, 396; language impairments and, 285; repairing later in life, 66
brain development, 56–65, 67, 73; in embryonic and fetal stages, *59*; experience and, 63–64; major changes to brain structures, 57–58; neuronal development, 60–63; neurons and neurotransmitters, 58–60; prenatal, timetable of, 58*t*; preterm births and, 48; puberty and, 64–65, 67; themes to consider in, 56–57; visual experience and, 83
brain-imaging studies: of psychopathy, *614*
brain mass: over lifespan, 58
brain metabolites: Alzheimer's disease and, 634
brain regions: cognitive empathy and activation of, 455; moral judgments and activation of, 446; schizophrenia and abnormalities in, 618
brainstem, 57, 58
brain volumes: heritability of, 399, *399*
branching direction, 280
breastfeeding: Freud's focus on, 190–91; suckling reflex and, 149

breast milk: infants' preference for sweet substances and, 107; many tastes in, 108; smell of, 109
bridge playing: aging and, *642*
brightness: perceiving differences in acuity and, 79–83; perception in infants, *79*
Britain: divorce rate in, *533*
British children: cosmological beliefs and, 336; imaginary companions and, 548
British school system: Eleven Plus exam and, 386, *386*
Broadbent, Donald, 359
Broca's area: aphasia and, 285
Bronfenbrenner, Urie: ecological systems approach of, 510, 544, 575
Brown, Ann, 413, 414, 415, 418
Bruer, John, 181
Bryant, Peter, 314
bulimia nervosa, 598, 602–3, 626; age of onset in, *602*; body distortions and, 600, *600*; causal factors in, 602–3; diagnostic features of, 599*t,* 602; incidence of, 602
bullies: characteristics of, 550; self-esteem in, 479, *479*
bullying, 547, 606; curbing, interventions for, 551; cyberbullying, 573–74; defined, 549–50; effects of, *550*; in schools, 550
bully-victim relationships, 549–51
Burt, Cyril L., 386
Bush, George H. W., 653
busing, 410

cable television, 560
CAH. *see* congenital adrenal hyperplasia (CAH)
calculations: numerical, frontal brain areas and, 169
caloric restriction: cognitive aging and, 640–41
Campione, Joseph, 413, 414, 415, 418
Canada: divorce rate in, *533*; fertility rates in, *528*; moral thought and individualist culture in, 442
Canadian children: conflict resolution, use of toys and, 575
canalization, 39; landscape of, *39*
capuchin monkeys: mirror test and, 472
car crashes: age and, 645, *645*
career achievements: intelligence test scores and, 390
caregivers: developing bonds between infants and, 188, 189–90, 224; smile of recognition and, 195–96
Carey, Susan: property attribution method and research of, 330
caring: gender differences and morality of, 440–41
Caro, Isabelle, *599*
Carroll, John: three-stratum intelligence theory of, 391, *392*
cartoon shows: television, negative cognitive effects of, 563, 564
Cast Away (film), 549
cataracts, 77; visual experience and, 77, 83, 96, 102
catastrophizing: anxiety disorders and, 594
categorical perception: of color, 84, *85,* 85–86; of speech, *104,* 104–5
categorization: basic level of, *316,* 316–17; essential features and, 175, *175*; in infants, *171,* 171–75; levels of, *174*
categorizing ability: perception, cognition, and, 77
category generation: creativity measured with, 417
catharsis hypothesis: violent television programming and, 564
cats: A-not-B error and, 163; categorization in infancy and, 175, *175*; critical period for developing binocular depth perception in, 88
Cattell, Raymond: fluid and crystallized intelligence theory of, 392
Cattell-Horn-Carroll (CHC) theory, of cognitive abilities, 391
causality: perception of, by 7-month-olds, 165, *165*
causal relationships: observational studies and, 23
causation: understanding, 164–66
cause and effect: questions about, experimental studies and, 23–24, 26
CBT. *see* cognitive-behavioral therapy (CBT)
Ceausescu, Nicolae, 216
Ce gene: anxious temperaments and, 248
cell phone texting: adolescent friendships and, 547
cells: death of, 61; differentiation of, 39–40, *45,* 70
centration: preoperational stage and, 310
cephalocaudal development, 44
cerebellum, 57, *57,* 58
cerebral cortex, 57; newborn and mature neuron in, *62*
cerebral hemispheres, 58
cerebral vesicles, 58
cerebrum, 57, *57*
certainty: teaching children about, 372
Chall, Jeanne: reading stages of, 372–73
change: qualitative, 9; quantitative, 10
characteristic features: word meanings and, 279
characteristic-to-defining shift: internalizing language and, 293
charter schools: e-learning and, 419
chat rooms, 572
cheating: by children in school, 448–49, *449*; consistency of, in Hartshorne's and May's study, 444, *445*
checking behaviors: OCD and, *595*, 596, 597
chemical senses: smell, 109; taste, 107–8, *108*
chess: learning to play, learning language *vs.,* 261, *261*; memory and experts in, 352–53, *353*
Chess, Stella, 249, 250, 252
chickens: imprinting in, 135–36; newborn, pecking at food by, 93, *93*; newborn, subtraction and, 169; pattern perception in, 92–93
child abuse, 505, 536–39, 541; corporal punishment and, 538, *538*; cycle of abuse, 537–38; effects of, 537; foster care and, 538–39; infant-parent bonds and, 192; interventions for reducing, 538; prevalence and patterns of, in U.S., 536; schizophrenia in Germain sisters and, 618; stepfathers, stepdaughters and, 535–36
childbearing years: effects from delay in, *525,* 525–26
child care: working parents and, 529–30
child custody, 534
child development: visiting nurses and, 51
child-directed speech, 101, 267–68, *268,* 269
child effects: parenting patterns and, *511,* 511–13, 540
child-environment interactions: goodness of fit and, 252–55
childhood disintegrative disorder, 590
childhood obesity, 116
child labor: development, social policy and, *6*
child neglect, 536
child prodigies: multiple intelligences and, 393
children: adopted, wide variation in outcomes for, 218; of authoritarian parents, 507; of authoritative parents, 507; average, 554; with bipolar disorder, diagnostic problems and, 609; changes in reward and control circuits in, *67*; in concentration camps, close peer bonds among, 215–16, *216*; controversial, 554, 557; depression in, 604; divorce and impact on, 533–35; effect of parenting on emotion processing in, 240–41; in English war evacuation residences, *216*; experimental research and, 25; family therapies and, 622; feral, 282, *282*; in foster care, 538–39, *539*; free speech and rights of, 570–71, *571*; with imaginary companions, 548–49, *549*; insecure attachment and, 206–8; neglected, 554, 557; of neglectful/uninvolved parents, 508; older parents and tradeoffs for, 526; parental conflict and, 534, *534*; parenting styles and behavior in, *507*; parenting styles and effects on, 508*t*; of permissive parents, 507; pervasiveness of television watching by, 560–61;

children (*continued*)
popular, 554, 555; prepared fear of snakes in, 243, *243*; psychoactive medications prescribed for, 623; rejected, 554, 555; rise of psychiatric drug use in, 622, *622,* 624; roles in larger culture and, 574–79; schizophrenia in, 615, 619; shared dispositions between parents and, 514; socialization process and participant of, 464; special needs, 6; of teenage mothers, 527; as "universal novices," 380; as witnesses, 360–61. *see also* families; parenting styles; parents; siblings
chimpanzees, 486; instrumental helping in, 451; invisible displacements and, 164; mirror test with, 471, *471*; sign language and, 288–89; social agents and, 182; theory of mind and, 484, 485
China: childhood obesity in, 116; market economy and childhood traits in, 576; moral thought and collectivist culture in, 442; one-child policy in, *522,* 522–23
Chinese American mothers: mean age for first births and, 527
Chinese-American parents, 509
Chinese children: conflict resolution, use of toys and, 575; early childhood amnesia and, 356
choice: mitigating negative effects of rewards and, 499, *499*
Chomsky, Noam, 269, 272; principles and parameters approach advanced by, 280
chromosomes, 36, 37, 41; gender identity and, 474; sexual differentiation and, *52*; telomeres and, 632
chums, 547, *547*
chumships, 547
chunking, 346
ciliary muscle, *78*
circadian rhythms: aging and, *641,* 641–42
circulatory system: rudimentary, 44
civil rights movement (1960s): busing and, 410
classical learning tradition: reinforcement-based views in, 430
classical music: newborns and, 106, *106*
classical (or Pavlovian) conditioning, 138, 593, 619–20; description of, 138–39; in "Little Albert" studies, 138–39, *139*; in sleeping newborns, *138*
classification (Piaget): in preschool children, *315,* 315–16
classification tasks: preoperational stage and, 310
class-inclusion relations, 315, 317
classroom: cognitive science ideas implemented in, 415–16
cleaning: compulsive, OCD and, *595*, 596, 597
clear-cut attachment phase, 193
Cleckley, Hervey, 610
cleft lip and palate, 54
clinging, 193; attachment complex and, 194, 196–97; in primates, 196, *197*
Clinton, Bill, 328; outgoing nature of, *643*; V-chip technology recommended by, *568*
cliques, 544, 553, 554, *554,* 555
CLP. *see* Community of Learners program
cochlear implants: critical periods for auditory processing and, 102
codominant alleles, 37
cognition: categorizing ability and, 77; explicit, 146; implicit, 146; social dominance and, 484, *485*
cognitive abilities: bilingualism and, 296–97; Cattell-Horn-Carroll theory of, 391
cognitive-behavioral therapy (CBT): studies of, 624; in treatment of childhood pathologies, 620–21
cognitive changes in adulthood, 635–42; circadian rhythms, cognition, and lifespan, 641–42; daily activities and, 639–41; memory, higher cognitive functions, and reasoning, 635–39; reaction time and speed of processing, 635
cognitive decline: sleep disorders and, 634
cognitive development, 8, *9*; day care and, 213; dimensions of, *305,* 305–7, 340; ecological approach to, 381; foundational *vs.* emergent, *305,* 306–7; global *vs.* local development, *305,* 306; language and influence of, 294–95; microgenetic analysis of, 377, 381; Piaget's four periods of, 148, 149*t,* 308–12, 309*t*; Piaget's theory of, 147–49; qualitative *vs.* quantitative development, *305,* 305–6; social deprivation in Romanian orphanages and, 217, *217*; understanding, 304
cognitive difficulties: preterm births and, 48
cognitive empathy, 455, 456
cognitive factors: in anxiety disorders, *594,* 594–95
cognitive functions: aging and, 635–39
cognitive maps, 321
cognitive patterns, in depression, 605–7
cognitive reserve: in elderly, 641
cognitive science: teaching and, 413
cognitive science perspectives: on development, 20, 22, *22,* 31
cognitive science themes: for education, 413–15; implemented in classroom, 415–16
cognitive skills: attention, 358–66, 382; growth of, 343–83; mathematical skills, 376–78, 382; memory, 344–58, 381; reading, 372–75, 382; reasoning, 366–72, 382; schooling and impact on, 413; using symbolic representations, 378–80
cognitive styles: parent-child interactions and, 556, *556*
cohabitation arrangements, 532
cohort effects, 27–28, 32, 645
colicky infants: attachment and, 207
collaborative learning: computer-supported, 419
collaborative repair: in conversation, 298, 299
collectivist cultures: moral thought and, 441–42; parents in, 575; rights of group in, 575; situational factors and, 493–94; stereotypes, ageism and, 655
College Board, 364, 366
college education investments: biological parents *vs.* stepparents and, 536
collision rates: by age, *651*
color, 84–86; categorical perception of, *85,* 85–86; number and, 291; perceiving hue and clustering of hues, 84
common fate: perceiving, 94, *94,* 95
communication: infants and universal properties of, 101; intentional, A-not-B task and, 156, *156,* 163; prelinguistic perception and, 263–64; schizophrenia and difficulties with, 616; stereotypes about elderly and, 654–55; theory of mind and, 492–93; turn-taking in, 298, 299
communicative condition: A-not-B error and, 156, *156*
community, 429; as moral value, 442
Community of Learners program (CLP), 413; computers used in, 418; effects of, 415, *415*
comparative perspective: on development, *17,* 17–18, 31
compensation, 656; aging and, 637–38; operator of, 309
compensation plasticity, 63
competence: elderly and perceptions of, 654
competition: cooperation *vs.,* 449, *449*
complex emotions, *231,* 233–35, 256, 257
complex reaction times, 635, *636*
comprehension skills: reading and, 372, 373, 374
computers, 569; age and use of, 572, *572*; e-learning and, *418,* 418–19; as "pedagogical agents," 419
concentration camps: close peer bonds among children in, 215–16, *216*
conception, 37, 43; later onset of schizophrenia and, 618, *618*
concepts: words linked to, 273–75
conceptual competence, 327
conceptual self, 470, 470*t,* 500
concrete operational period (Piaget), 148, 149*t,* 308, 309*t,* 311
conditioned response (CR), 138, 139
conditioned stimulus (CS), 138, 139
conditioning, 136, 138–42; classical, 138–39; constraints on learning, 140–42; operant, 139–40

conduct disorder(s), 454, 587; case of psychopathy, 609–14, 626; diagnosis of, 609, 610*t,* 611–12; diagnosis of bipolar disorder as distinct from, 609; family therapies and, 622
confidentiality: experimental research and, 25
confirmation and fluency stage: in reading, 373
conflict: adolescent romantic relationships and, 552; anorexic families and avoidance of, 601; between siblings, 520–21; in social interactions, dealing with, 545
conflict resolution: siblings and, 521, 524, *524*
confluence theory: birth order effect on intelligence and, 518, 519
congenital adrenal hyperplasia (CAH): girls with, play with gender-atypical toys and, 516–17
conscience: delay in gratification and, 480; parent-child interactions and development of, 462–63
conscientiousness, 643, 644; group changes in, *648*
consent: experimental research and, 25
consequences: generating, creativity measured by, 417
conservation tasks: alternative explanations of, 317–20; failure on, young children and, 313, *313,* 436; preoperational stage and, 309, *310*
consolidation: neuron development and, 60, 61–62
constraints: domains of knowledge and, 320; on learning, 140–42; Spelke's studies on infants' awareness of, 160–61; on word meanings, 275–78
constraints on development, 35–36, 38–41; differentiation of cells and structures, 39–40; timing and sequencing, 40–41; viability, 38–39
construction and reconstruction stage: in reading, 372, 373
constructivist approach: to moral reasoning, 442
consumerism: television and norms of, 569
contact: infants' understanding of physical world and, 160, *160,* 161
contact comfort: Harlow's studies of infant monkeys and, 219, *220*
contact principle: infants' understanding of, 335
contamination: OCD and fears of, *595*, 596
context: goal attribution and, 180, *180*
contextual influences: on self-regulation, 481–82
contingent responding, *195,* 199, *199*
continuation, 95
continuity, 335; infants' understanding of physical world and, 160, *160,* 161, 162
contour information: ambiguous, in an artificial environment, *322,* 322–23; navigating with, 322, *322*
control: authoritarian parents and, 507, 508*t*; authoritative parents and, 507, 508*t*; high/low, parenting styles and, 506, 506*t*; neglectful/uninvolved parents and, 508*t*; parents' perceptions and, 513; permissive parents and, 507, 508*t*
controversial children, 554, 557
conventional level of morality: in Kohlberg's stages of moral development, 437–38, 438*t*
conventional stage: in Gilligan's theory of moral development, 440, 440*t*
conventions: morality *vs.,* 435
convergence, 87, 88; cues, 87–88; in the distance, 88, *89*
converging methods, 28, 32
conversational norms: across cultures, 298
"cool" popular children, 555
cooperation: competition *vs.,* 449, *449*
coordination: in changing bodies, 122–23
core domains, 320
cornea, 78, *78*
corporal punishment: child abuse and, 538, *538*
corpus callosum, 57, *57*
correctionism: defined, 270
correctionist approaches: to language acquisition, 270
cortex, *57*
cortisol: early deprivation and levels of, 221; infants' stress response, failure in attachments and, 217–18
co-rumination: friendships and, 548; gender, depression, and, 608
cosmological beliefs, 336, *336,* 369
cotton-top tamarins: linguistic patterns distinguished by, 100
counterempathy, 456
counting, 376; preschoolers and limitations on, 324–25, *325*; understanding, *324,* 324–25
counting all strategy: for addition, 376
counting behaviors: OCD and, *595*, 596, 597
counting on strategy: for addition, 376
counting up strategy: for multiplication, 377
coyness, 234
CR. *see* conditioned response (CR)
cradleboarding: motor deprivation in Hopi infants and, 119, *120*
crawling, 125; carrying objects while engaging in, 130, *130*
creative abilities: successful intelligence and, 394
creativity, 417–21, 423; attribution, motivation, and, 497–99; extraordinary, development of, 420–21; measures of, 417–19
criminality: antisocial behaviors leading to, 453
critical periods: American Sign Language acquired after, 283; for auditory processing, cochlear implants and, 102; for developing binocular depth perception, 88; in development, 35; grammatical ability and, *281*; imprinting, action, and, 135–36; language acquisition and, 281–84; myth of first 3 years and, 181; processing acuity and, 83; social deprivation and, 222–23; in songbirds, 135; stereopsis and, 88
critical thinking, 6
cross-cultural perspectives: on development, *18,* 18–19, 31
"cross-eyed" condition: critical-period effect and, 88
crossing-over: genetic diversity and, 42
cross-sectional approaches, 32; longitudinal approaches *vs., 27*; strengths and weaknesses with, 27–28; tradeoffs with, 29*t*
crossword puzzles: aging and solving of, 637, *637*
crowds, 554
crying, 193
crystallized intelligence, 392; aging and fluid intelligence *vs., 636,* 636–37
CS. *see* conditioned stimulus (CS)
cueing hypothesis: infantile amnesia and, 354–55
cues to depth: binocular, *87,* 87–88; dynamic, *86,* 86–87; pictorial, 88–89, *89*
cultural learning, in schools, 411–12
cultural psychology: morality and, 429; moral thought and contributions from, 441–42
culture of honor: in southeastern United States, *574,* 574–75
culture(s): anorexia nervosa across, 599–600; biological explanations and, 332; biological knowledge and exposure to nature in, 333, *333*; bulimia across, 602; child-directed speech and, 268; color perception across, 85; contingent responding and, 199; conversational norms across, 298; core biological beliefs and, 327–29; counting across, 325, *326*; culture of honor in the South, 574, *574*; disgust category and, 246; display rules and, 239; distinctive cultural and subcultural roles, 574–76; drawing and conventions of, 380, 382; early childhood amnesia and, 355–56; emergence of early biological thought and, 337; guilt and, 233; immanent justice across, 436–37; Kohlberg's stages of moral development across, 439; moral beliefs across, *430*; moral reasoning and, 464; moral thought and, 441–42; narrative skills across, 298–99;

culture(s) (*continued*)
negative effects of extrinsic rewards and, 499; numbers and, 166; older adults and complexity of, 633; parent-child bonding and, 204; parenting across, 508–10; politeness mechanisms across, 298; punishment studied across, 460; roles in larger culture, 574–79, 583; schizophrenia across, 618; schools characterized across, 409–10, *410*; self-regulation across, 482, *482*; shame, 233; single-parent families across, 530, 531*t*; television viewing across, 560, *561*; variation in stereotypes and ageism across, *655,* 655–56
"cuteness": attachment complex and, 194, 197–98, *198*; baby features leading to perception of, *198*; variations in, *198*
cyberbullying, 573–74
cycle of abuse, 505, 537–38, 541
cytosine: DNA double helix and, 36, *36*

daily activities: cognitive aging and, 639–41
Damon, William, 464; moral development theory of, 442, 443
Dann, Sophie: studies of children who grew up in concentration camp, 215, 220
Darwin, Charles, 245, 420*t*; infant facial expressions studied by, 229, *229*
Darwin, William (Doddy), *229*
dating, 546, 552–53
Datoga fathers (Tanzania), 204
day care: attachment style and, *212,* 212–13; working parents and, 529–30
day/night cycle: explanatory processes related to, 369, *370*
DCDC2 gene: dyslexia and, 375
deaf children: inventing new language and, 284, *284*; language learning and critical-period effects in, 283
deaf infants: babbling in, 264
deafness: compensation plasticity and, 63; organ of corti damage and, 102
decision tasks: complex, aging and, 639
declarative memory, 347–48
decoding, 373, 380
defining features: word meanings and, 279
delay in gratification, 453, 477; age and differences in, *477*, 479–80; self-regulation and, 477, 478
delusions: schizophrenia and, 614, 619
dementia, 634; voting rights and, 650–51
dendrites, 59; of nerve cell, *59*
dendritic spines, 59
dependency: attachment *vs.,* 194
dependent variables, 24, 32
depressed mothers: anxious children and, 593–94; emotional regulation in children of, 245
depression, 6, 587, 603–9, 615, 626; ADHD and, 365; in adolescence, factors contributing to, 607, *607*; in adolescence, rise of, *604*; anorexia nervosa and, 599; Beck's work on, 606, 620; bipolar disorder, 603, 607–9; break-up of romantic relationships and, 553; child abuse and, 537; childhood, 604; children in orphanages and foster home care and levels of, 218; co-rumination, gender, and, 608; divorce in childhood and, 534; family therapies and, 622; learned helplessness and, 606; overview of, 603–4; rejected children and, 557; shame and, 462; stressful life events and, 644; unipolar, 603, 604–7
depressive phase: in bipolar disorder, 603, 607
depressogenic vulnerability, 607, *607*
deprivation: brain development and, 64
deprivation studies in nonhuman primates, 218–22; peer-raised infants, 220–22; tactile stimulation and physiological needs, 218–20
depth perception, 86–91, 123; cues to depth, 86–90; Gibson's visual cliff studies, 90–91; qualitative change in, 11, *11*
depth perception system: functional significance of, 91
DES. *see* diethylstilbestrol (DES)
Descartes, René, 15
desensitization: to television violence, studies on, 566
development: of action, 8, *9*; anatomical, 44–50, 52–55, 72–73; areas of, 8–9; basis of, 35–36, 72; beginnings of, 41–44, 72; behaviorist perspectives on, 19; of brain, 56–65, 67, 73; cognitive, 8, *9*; cognitive science perspectives on, 20, 22; comparative and evolutionary perspectives on, 17–18; constraints on, 38–41; critical periods in, 35; cross-cultural perspectives on, 18–19; emotional, 9, *9,* 228–47, 257; empiricist and nativist perspectives on, 14–17; as means for insight into the mature form, 5; media influences on, 559–74, 582; moral, 8, *9*; nature of, 6–14, 31; neuroscience perspectives on, 19, *19*; perceptual, 8, *9*; periods of, *7,* 7–8; perspectives on, 31–32; psychoanalytic perspectives on, 20; qualitative *vs.* quantitative, 9–10, *10*; reasons for studying, 4–6, 31; social, 8–9, *9*; social policy and, 6; stages of, 10; as a systems problem, 35; teratogens and, 54–55, 55*t*; understanding children's capabilities and, 4–5. *see also* biology of development; development and social policy; language development
developmental intergroup theory, 577
developmentally delayed children: highly directive instruction and, 417
developmental patterns: understanding, 4, 5
developmental psychology, 3–4; attachment in, 192; viewing as study of emerging competencies, 422
development and social policy: accelerating toddler's motor development, 137; age of offender and treatment as an adult, 457, *457*; children as witnesses, 360–61; computers and e-learning in the schools, 418–19; day care and attachment, *212,* 212–13; depriving elderly of some rights, 650–51; free speech and children's rights, 570–71, *571*; justified experimental research, 25; legislating early stimulation, 106, *106*; myth of first 3 years, 181; potential drawbacks of self-esteem, 478–79; prescribing psychoactive medications to young children, 623; visiting nurses, prenatal care, and child development, 51
devil's tuning fork, *92*
Dewey, John, 410
dexoyribonucleic acid. *see* DNA (deoxyribonucleic acid)
DHEA: qualitative changes during puberty and, *11*
diabetes, 40; heritability and, 68
Diagnostic and Statistical Manual of Mental Disorders (DSM): revision of, 589–90
diathesis-stress hypothesis, 592, 605
diencephalon, 58
diet, 656; aging and, 635; cognitive aging and, 640–41; healthy aging and, 631; methylation and, 40, *40*; pregnancy and, 39–40
diethylstilbestrol (DES), 54
differentiation: for cell types and anatomical structures, 38–39; first patterns of, 43–44; successive, 46
difficult babies: environments for, 253; in New York Longitudinal Study, 249; parental influences and, 253, 254
digital video: observational studies and, 23
directions: encoding, linguistic relativity and, 292
disadvantaged children: day care, attachment and, 213; IQ scores and, 403
disadvantaged groups: sociocultural influences on, 405
discipline, 505–6
discipline-based expertise, 372
discrimination: IQ scores and, 403; racial and ethnic occupational stereotypes and, 578, *579*; same-sex couples and, 552
disgust: bitter taste and, 246, *247*; facial expression in infant, *232*; goal and action related to, 230*t*; preparedness and development of, 244–47, *247*; toward feces, 245–46
dishabituation, 80, 136; action at a distance study and, 176, *176*; addition in infants and, 168, *168*; categorical perception of

color and, 85; categorization, essential features and, 175, *175*; causal interpretations and, 165; idealized example of, *81*; “impossible” physical events and, 159, *159* 164–65; numerical competency and, 167; sound patterns and, 105; understanding permanence and solidity by 4-month-old infants and, *158,* 158–59
“disinhibited” forms of attachments: reversing, difficulty in, 222; in Romanian orphans, 217
disorganized attachment: Type D infants and, 203
disorganized symptoms: of schizophrenia, 615
display rules, 239
dispositional factors, 493, 494
distraction, 239
distress: emotional contagion and, 237
diversity: educational television programs and, 563; out of uniformity, 49–50
divinity: as moral value, 442
divorce, 505, 532–35, 540, 541, 644; adoptive *vs.* biological families and, 535; educational levels and rates of, *532*; increase in, 532; rates of, across different countries, 532, *533*
dizygotic (DZ) twins, 43; anorexia and concordance rate for, 601; autism and concordance rate for, 591; criminality studies of, 453; genetics of early handedness and, 124; heritability of brain volumes in, *399*; heritability of intelligence and, 398; OCD in, 598; studies of, *67*; unipolar depression in, 604
DNA (deoxyribonucleic acid), 36; aging and, 632; behavioral genomics and, 68; double helix, 36, *36*; homeobox and, 50; stress response and methylation of, 221, 222
Dobermans: attacking by, *16*
dogs: A-not-B error and, 163, *163*; effectiveness of punishment with, 458, *458*; object solidity and, 164, *164*; temperament and breeds of, 251, *251*; theory of mind in, 486, *486*
domain-general cognitive capacity, 306
domain-general theory (Piaget), 320
domains of knowledge: biology, 327–34, 340; cosmology, beliefs about, 336, 340; number, 324–27, 340; physical mechanics, beliefs about, 335–36, 340; spatial relations, 321–24, 340; substance, beliefs about, 336, 340
domain-specific cognitive development, 306, 339
domain specificity of language, 284–86, 288–90, 301; neural dissociations, 285–86, 288; species specificity, 288–90
domain-specific learning, 415
domain-specific moral reasoning, 442–44
dominance hierarchies, 484; in social groups, 553
dominant alleles, 37
Donaldson, Margaret: number conservation tasks studies of, 317–19, *319*
dopamine: ADHD and deficits in, 365; epigenetics, parental care and levels of, 513; executive functioning and, 361
dorsolateral prefrontal cortex: A-not-B task and, 156–57, *157*
double dissociation: between two cognitive abilities, 286
double helix: DNA, 36, *36*
Down syndrome: insecure attachment and children with, 207; maternal age and, 591; trisomy 21 and, 42, *42*
“drawbridge study”: object solidity and, *158,* 158–59
drawings, 382; age and skill in, 380, *380*; symbolic representations in, 379–80
DRD4: temperament, attachment and, 208
driving: elderly rights and, 650; on right/left side of road, social conventions and, 435, *435*
drone aircraft operation: video game skills and, 570
dropped ball study (Spelke), 160–61, *161*
drug abuse: preterm births and, 48
drug treatment: for childhood psychopathologies, 622–24
DSM. *see Diagnostic and Statistical Manual of Mental Disorders* (DSM)
DSM-IV, 590
DSM-IV-TR, 590
DSM-V: diagnostic criteria for autism in, 590
dual representations: models as, 378, 379
ducks: imprinting in, 135–36
Duncker, Karl, 417; functional fixedness study of, 417, *420*
Dutch children: emotional suppression and, 239
Dutch speakers: spatial representations and, 292, *293*
dynamic cues: to depth, *86,* 86–87; emergence of, 91, *91*
dynamic systems theory: of motor development, 120–22
dyslexia, 307, 374–75, 382; ADHD and, 365; genetics of, 375; reading and, 374–75

early childhood amnesia: culture, gender, and, 355–56
early competence accounts, 329, 332
early development factors: schizophrenia and, 618, *618*
Early Head Start, 409; parenting interventions and, 510, 511
early intervention programs: myth of first 3 years and, 181
early school-age children: self-esteem in, 475, 476*t*
early stimulation: legislating, 106, *106*
earth: children’s models of, 369–70, *370*
easy babies: in New York Longitudinal Study, 249; parental influences and, 253
eating disorders, 587, 598–603, 615, 626; anorexia nervosa, 598–602; binge eating, 598; body distortions by those with, 600, *600*; bulimia nervosa, 598, 602–3; incidence of, 598; introduction of television into rural Fiji and, 569, *569,* 599
echoic memory, 345
echolalic speech, 589
ecological approach to cognitive development, 381
ecological self, 469, *469,* 470*t,* 472
ecological systems approach, 544, 575; to families, 510
ecological validity, 24, 32
economic effects: group differences, intelligence tests, and, 403
ectoderm, 44, 58
edge alignment, 95
education: bilingual, 297; cognitive science themes for, 413–15; computers and e-learning and, *418,* 418–19; Dewey model in, 410; platoon school, 410–11
educational television programming: positive effects of, *562,* 562–63
EEGs. *see* electroencephalograms (EEGs)
egg cells, 41, 42
ego, 462, 469
egocentric representation, 169
egocentrism, 169, 170, 294, 295; spatial relations and, *321,* 321–22
Einstein, Albert, 421
Eisenberg, Nancy, 464; on altruistic stages of reasoning, 443; empathy in prosocial behavior theory of, 454
elderly people: bridge playing by, *642*; cognitive reserve in, 641; complex decision making and, 639; cross-cultural views of, *655,* 655–56; dementia in, 634; depriving of some rights, acceptability of, 650–51; source monitoring difficulties in, 638–39; stereotypes of, *654,* 654–55
elderly population, cultural complexity and, 633
e-learning: computers in schools and, *418,* 418–19
elective mutism: autism and, 588
Electra conflict, 462
electroencephalograms (EEGs): mirror neurons, early imitation and, 134; studies of children exhibiting psychopathy-related behaviors, 613

elementary school children: beliefs about physical mechanics and, 335; enemies among, 551; evolving nature of knowledge and, 372; mathematical skills and, 376; social groups among, 553; social interactions among, 545–46
Eleven Plus exam (British), 386, *386*
elicited imitation tasks, 347
Eliot, T. S., 420*t*
e-mail, 572
embarrassment, 233, 234
embryo, 44; implantation of, *46*; structures and systems in, 44–47
embryonic period, 44–47, *46*; terataogens and, 54; timing and teratogen's influence in, *56*
emergent constraints: foundational constraints *vs.,* 306–7, *307*
"emotional availability": in parent-child relationships, 245
emotional contagion, 237, 257
emotional development, 9, *9,* 228–47, 257; approaches to, 229–30; differentiation of emotions in infancy, 230–35; emotional preparedness and, 242–47; emotional regulation in infancy, 237–41; evolutionary preparedness and, 242–47; perceiving and thinking about emotions, 236–37
emotional empathy, 455, 456
emotional intelligence, 244; *g* for and levels of, 395
emotionality, 248
emotional regulation, *242,* 257; aging and, 639; attentional deployment and, 238, 239, *242,* 245; causes and consequences of problems in, 244–45; empathy and, 456; gene-environment interactions and, 254; in infancy, 237–41; psychopathy, neural deficits and difficulties in, 612; response modification and, 238, 239–41, *242*; situational factors and, 238–39, 240
emotional stability: group changes in, *648*
emotional states: managing, 395
emotion perception: abused children and, 240–41, *241*
emotion recognition: psychopathy and deficits in, 612
emotions: adaptive value of, 255; basic, 230–33; complex, *231,* 233–35, 256, 257; defined, 228; differentiating, in infancy, 230–35; differentiation of, in first 3 years of life, *231*; evolution and development of, *233*; functionalist approach to, 230; goals and, 230*t*; human attachment and, 192; inferring actions from, 238, *238*; Machiavellian, 234; moral, 235, 430; physiological, cognitive, and behavioral components of, 228–29; recognizing in others, 236–37; self-conscious, 233
empathy, 233, 237, 395, 429, 430, 443, 452, 454–56, 580; autism and seeming lack of, 588; cognitive, 455; different degrees of, 455, *455*; emotional, 455; emotional regulation and, 456; fostering, prosocial television programs and, 563; in girls' friendships, 547; motor, 455–56; psychopathy and lack of, 610, 612, 614; St. Francis of Assisi and, *431*; violent video games and decrease in, 572
empiricism, 15, 31, 32; correctionist approaches and, 270, 272; Piaget and, 149; Whorfian view and, 290
empiricists: categorization in infancy and, 171–72; eye-limb coordination and, 123; intelligence tests and, 422; principles of how infants understand and, 161
employment: intelligence test scores and level of, 390
encoding, 345
enculturation: in schools, 411–12
endoderm, 44
enemies: aggression between, 551–52
engineering model, 312
English language: gender markings in, 292
English verbs: forming past tense for, 266–67, *267*
enmeshment: anorexic families and, 601
enriched environments: brain development and, 64
enrichment programs, for toddlers, 137
entertainment television programming: negative cognitive effects of, 563–64
environment: animal behavior and, 141–42; anorexia nervosa and, 601; autism and, 591–92; biological system and, 37; brain development and, 63–64; classroom, 409; cycle of abuse and, 537–38; development and, 35; feedback loops between infants and, 77; Flynn effect and, 407; genes and, 38, 69; goodness of fit between child and, 252–55; heritability and, 68; heritability of intelligence and, 398, 399; intelligence test scores and, 407–9, 423; "nature/nurture" debate and, 13, *14*; phenotype and, 42; sex differences in intelligence and, 401; social contexts in, 544; for "squeaky wheels," 253
environmental niches, 36
envy, 233
epigenetics: families and, *512,* 512–13; regulation in, 39
epilepsy: mirror neurons, imitation and, 134
episodic memories: narrative skills and development of, 358*t*
episodic memory, 348; aging and, 639
equilibration, 147, 148, *148*
equivalences, 315
Erikson, Erik, *649,* 652; stages of psychosocial development by, 648–52, 649*t,* 652, 658
ERPs. *see* event-related potentials (ERPs)
error correction/shifting: executive functioning and, 361
Eskimo-Aleut languages: analysis of, 290–91
essentialism: in young children, 334
essentialist bias, 494
estimating numerical differences: parietal regions of brain and, 169
estradiol: qualitative changes during puberty and, *11*
estrogen: sexual differentiation and, *52*
ethnic differences: intelligence test scores and, controversy over, 402
ethnicity: of children in foster care, *539*; divorce rates and, 532; exclusion based on gender *vs.,* 516; family size in U.S. and, 527, 528*t*
ethnic occupational stereotypes: development of, 578, *579*
ethological approach: to attachment, 192–94; attachment behaviors and, 188; deprivation and, 189; social bonds and, 223
ethology, 18, 32; development of, 192
Europe: television viewing studies in, 560
European-American children: early biological thought in, 337; self-esteem in, 478
European-American parents: parenting interventions and, 510
European Americans: awareness of stereotypes, intellectual abilities and, 406; Flynn effect and, 406, 407; IQ scores and, 402, 403; racial and ethnic occupational stereotypes and, 578, *579*; stereotype threat and, 405
European Union: physical punishment studied in, 460
evaluative information: long-term autobiographical memory and, 357
evaluative reasoning, 494–95; defined, 494; trait-based reasoning *vs., 494*
evaluativist perspective, 372
event-related potentials (ERPs), 483; large *vs.* small-number operations and, 169; self-regulation and, 481
evidence: teaching children about, 372
evidence-based therapy: evaluating, 624
evolution: as a branching tree, *49*; facial attractiveness and, 99–100
evolutionary perspective on development, *17,* 18, 31
evolutionary preparedness: emotional development and, 242–47
evolutionary psychology: morality and, 429
executive functioning, 349; attention and, 359, 361–63; at the street corner, 363, *363*
executive processing: aging and, 638

executive tasks: exercise, aging and, *640*
exercise, 656; cognitive aging and, 640, *640*; healthy aging and, 631; social network effects and, 558
experience: brain development and, 63–64
experience-dependent plasticity, 64
experimental research: justification for, 25
experimental studies, 23–24, 26, 32, 581; on television influences and children, 560; tradeoffs with, 29*t*; on violent television programming and aggression, 564, 566
expertise: aging and niches of, 637; discipline-based, 372; goal-centered, 372; memory and, 352–53
explanation application, 369
explanation expansion, 369
explicit cognition, 146
explicit memory, *347,* 348; aging and, 639
extended families, 528–29
extended self, 469, 470*t,* 500
externalizing problems: boys' responses to divorce and, 533
external validity, 29–30
extremely premature infants, *48*
extrinsic rewards: self-perception, motivation, and, 497–98, 499
extroversion, 643
eye gaze: theory of mind and, 483, 484, *484*
eye-limb coordination: empiricist view of, 123
eyes: aging of, 634; constraints on links between limbs and, 123–25; growing into focus, 82–83, *83*; innate specializations in, *78*
eye tracking: methods in infants, advances in, 172–73, *173*; as window into functional understanding, *173*

face area: in brain, emergence of, 98, *98*
Facebook, 572
face perception, 95–100, 142; caregiver's gender and, 97; development of, two-system model, 97–99; happy faces *vs.* fearful faces, 96; normal *vs.* scrambled faces, 95, *95*; race and, 96–97; same-race processing bias and, 96–97; scrambled but symmetrical faces, *96*; tracking moving faces, 97, *97*; two-system model and, 136
facial attractiveness, *99,* 99–100
facial expressions, 237; in basic emotions in infants, *232*; imitation by infants, *131,* 131–32; imitation in newborns of other species, 132–33, *133*; infant, coding systems and research on, 229–30, *232*; infant, Darwin's studies of, 229, *229*; situation modification and, 239; taste perception and, 107, *108*
factor analysis, 391, 643
fairness, 429
fairness/reciprocity moral module, 443*t,* 444
false beliefs, 182, 483; understanding, 178, *179,* 487–90, *488*
false-belief tasks, 178, 483, 500; evaluating, 489–90; variations on, 489
false memories: children as witnesses and, 360–61
false-photograph task, 489
families: anorexic, 601–2; blended, 535–36; bulimia and influence of, 602–3; changes in, 541; changes in parents' age, 525–27, *526*; changes in size of, 527–28; ecological systems approach to, 510; epigenetics and, *512,* 512–13; ethnicity and size of, in U.S., *528*; extended, 528–29; foster, 538–39, *539*; gender socialization in, 515–18, *516*; nuclear, 528; parents and, *505*; working parents and child care, 529–30. *see also* children; parenting styles; parents; siblings
family dynamics: interactionist approach to, 514–15; siblings and, 518–21, 524–25, 541
family size: children's IQ test scores and, 408; decline in, 653; in different countries, 527, *528*
family structures: blended families, 535–36; changes in, 530–36; divorce, 532–35; same-sex parents, 530–32, *532*; single-parent families, 530, 531*t*
family therapies: in treatment of childhood psychopathologies, 622
famine: thrifty phenotype hypothesis and, 34
fast mapping, 274
fast-twitch muscles: aging and decline in, 631
father-infant bonds, 191
fathers: child care and, 529, 530; as custodial parents, 534; insecure attachment and attitude of, 206; new insights into role of, 204–5, *205*; sexual abuse by, 536
fear conditioning, 619–20
fear processing: psychopathy and, 613, *613*
fear(s), 70, 231, 233, 249, 430; acquiring, preparedness for, 242–44; conditioning of, in "Little Albert" studies, 139, *139*; facial expression in infant, *232*; goal and action related to, 230*t*; in infants, 142; inhibited infants and, 251; learning to associate snakes with, *246*; prepared, 242–43, *243*
feedback loops: attachment style and, 208; difficult babies and, 254; *5-HTT* gene, stress and, 221; between infant and environment, 77; perception, action and, 122; psychoactive medications for children and, 623; smile of recognition and, 195–96
females: adolescent, unipolar depression in, 604; Gilligan's theory of moral development and, 440–41, 440*t*; memory tasks and, 401, *401*; schizophrenia in, 615; sexual differentiation and, 52; spatial skills and, 400, *401. see also* girls; women
feral children: language and, *282,* 282–83
fertility: delayed childbearing and, 526
fertility rates: in Canada and U.S., *528*
fertilization, 42, 43, *43*
fetal alcohol syndrome, *56*; ADHD and, 365
fetal period, 46–47; timing and teratogen's influence in, *56*
fetus, 46–47; environmental influences on, 37; structures and systems in, 44–47
Fiji: introduction of Western television programming and eating disorders in, 569, *569,* 599
filtering: attention and, 359
fingers: number of, *52*
Finland: conversational norms in, 298
Finnish language: sparse gender markings in, 292
First Amendment, 571
firstborn children: parental influence on gender roles and, 518; sibling jealousy and, 520–21
"first child as the first draft" effect, 521
fish: mercury-contaminated, 54–55
5-HTT gene: long *vs.* short version of, serotonin levels and, 221
5-HTT pathways: attachment style and early changes in, 222
fixed-trait theorists, 497
flexibility: in developmental process, 34
fluid intelligence, 392; aging and crystallized intelligence *vs., 636,* 636–37
fluoxetine, 622, 624
Flynn, James, 406
Flynn effect, *406,* 406–7, 421; in rural Kenya, 407, 407*t*
fMRI studies: on autism, 590; of infants' brain activity, 21, *21*; mirror neurons, early imitation and, 134; on psychopathy, 612
Fodor, Jerry, 491
folk biology, 18, 327
folk physics, 327, 335
folk psychology, 327
follicle-stimulating hormone (FSH): qualitative changes during puberty and, *11*
forbidden thoughts: OCD and, *595,* 596
forebrain, 58
formal mental tools (operators), 309
formal operational period (Piaget), 148, 149*t,* 308, 309*t,* 311–12, *312*
foster care, 505, 538–39, 540, 541; psychiatric drug use and children in, 624; siblings and, 525

foundational constraints: emergent constraints *vs.,* 306–7, *307*
foundling babies: classes of deficits in, 214–15
fovea, *78*
FOXP2 gene: language deficits and, 287
fractions, 376
France: divorce rate in, *533*
Francis of Assisi (saint), *431*
fraternal twins, 43; heritability of intelligence and, 398
free speech: children's rights and, 570–71, *571*
Freud, Anna, 220, 621, 648; studies of children who grew up in concentration camp, 215–16
Freud, Sigmund, 20, 188, 190, 191, 222, 420*t,* 621; catharsis hypothesis of, 564; "Little Hans" case of, 593; moral development theory of, 462
friendships, 546–48, *547*; advantages and disadvantages of, 548; finding strength in, 544; Internet communities and, 572–73
frogs: pattern perception in, 93–94; perceptual-motor coordination in, 122, *122*
frontal lobes of brain, 57, *57*; heritability for volume of, 399, *399*; inhibition and, 480; puberty and, 65; self-regulation and maturation of, 481
FSH. *see* follicle-stimulating hormone (FSH)
functional fixedness, 417, *420*
functionalist approach: to emotion, 230
functional magnetic resonance imaging studies. *see* fMRI studies
functional neuroimaging: measuring infants' brain function and, 21
fundamental attribution error, *493,* 493–94

Gage, Phineas, 480, *480*
gametes, 42
Gardner, Howard: creativity proposals of, 420–21, 420*t*; multiple intelligences theory of, 393–94, 393*t*
gastrulation, 43, 44
gay and lesbian parents, 530–32, *532*
gaze following, 200–201; in human infants and great apes, 485, *485*
geese: imprinting in, 135–36, *136*
gender: ADHD and, 364; anorexia nervosa and, 599; anxiety disorders and, 592; Asperger's disorder and, 590; autism diagnosis and, 590; brain anatomy and, 401; child abuse and, 536; co-rumination, depression, and, 608; cyberbullying and, 574; depression, stressful life events and, 644; early childhood amnesia and, 355–56; eating disorders and, 598; enculturation in schools and, 411; exclusion based on ethnicity *vs.,* 516; face perception and, 97; friendships and, 547; Gilligan's theory of moral development and, 440–41, 440*t*; intelligence tests and, 400–402; job status and, 578, *579*; language-based tasks and, 401; memory tasks and, 401; narrative skills and, 298–99; phobias and, 244; presocialization toy preferences and, 517–18; schizophrenia and, 615; socialization across cultures and, 575; stereotyping in media and, 568; toy preferences and, in vervet monkeys, 517, *518*; unipolar depression and, 604. *see also* boys; females; girls; males; men; women
gender biases: possible, in Kohlberg's stages of moral development, 439–40
gender identity, 472–74, *473*; gender role or gender object choice *vs.,* 474
gender markings: influence of language on thought and, 292
gender object choice, 474
gender roles, 473, 474; stereotyping and, 576–79
gender role socialization: depression in girls and, 605
gender schemas: defined, 515
gender socialization: in families, 515–18, *516*
gene effects: model of, *69*; twin study approach and, 69
gene-environment interactions: emotional regulation problems and, 254
gene expression profiles, 68
general intelligence *(g):* for emotional intelligence, 395; heritabilities of intelligence linked to, 400; research on and debate over, 391–92; Spearman's theory of, 390
generalized anxiety disorder, 592–93, 595; earliest signs of, 593
generativity: language and, 262
generativity *vs.* stagnation: in Erikson's stages of psychosocial development, 649*t,* 651
genes: anxiety disorders and, 595; biological system and, 36–37; defined, 36; environment and, 38; heterochronic, 40; homeobox, 50, *50,* 71; pleiotropic effects and, 69; protein-coding, 36; study of intelligence and, 397–400
genetic diversity: meiosis and, 42
genetic effects: parenting and, 513–14
genetic factors: group differences, intelligence tests, and, 403
genetics: anorexia nervosa and, 601; autism and, 591; criminality and, 453–54; of dyslexia, 375; empathy and, 455; obsessive-compulsive disorder and, 598; psychopathy and, 613; of schizophrenia, 616–17; unipolar depression and, 604–5
Genie, language acquisition and, 282–83, *283*
geniuses: common patterns shared by, 420–21
genome, 36, 50
genomics: behavioral, 68–70
genotype, 38
geometric cues: cross-species use of, 170–71; spatial knowledge in infants and, 170, 171
geometric figures: goals attributed to, 178
geometric information, *322,* 322–23, 324
geometric properties of environment, 170
Germain quadruplets: different degrees of schizophrenia in, 617, 618
German children: emotional suppression in, 240
German language: masculine and feminine terms in, 292
German mothers: contingent responding and, 199
Germany: attachment styles in, 211, 211*t*; divorce rate in, *533*
Gesell, Arnold, 119, 137
Gestalt principles, 94
gestational age: preterm births and, 47
g (general intelligence), 390; for emotional intelligence, 395; heritabilities of intelligence linked to, 400; research on and debate over, 391–92
Gibson, Eleanor J., 120, 126; novel surfaces study by, 129, *130*; visual cliff studies by, *90,* 90–91
Gibson, James J., 120, 469
gifted children: aptitude-treatment interactions and, 417
Gilligan, Carol, 431, 439, 442, 464; moral development theory of, 440–41, 440*t*
girls: adolescent romantic relationships and, 552; anorexia nervosa in, 599; anxiety disorders in, 592; autism diagnosis for, 590; bulimia in, 602; with congenital adrenal hyperplasia, 516–17; co-rumination hypothesis and depression in, 608; countering stereotype threat, math task performance and, 405, *405*; cyberbullying and, 574; divorce and impact on, 533; eating disorders in, 598; effects of parental socialization on, 516*t*; fetal testosterone and diagnosis of autism-related symptoms in, *590*; in Fiji, television programming and eating disorders in, 569, *569*; friendships and, 547; gender role socialization and depression in, 605; language-based tasks and, 401; one-child policy in China and ratio of boys to, 523, *523*; parenting styles and effects on, 508*t*; presocialization toy preferences and, 517–18; qualitative physical changes during puberty and, 10; relational aggression and, 547, 551, *552,* 556; rumination and depression in, 607; sex differences in intelligence

and parental interactions with, 401; sex-stereotyped toys for, 515; sexual abuse of, 536, 537; stepparents and, 536; stereotyping of, in media, 568, 569; toy preferences in, 516
glial cells, 60; nerve cell regeneration and, 66
global changes, 32; in development, 11, 12
global patterns of development: local patterns of development *vs., 305,* 306
goal attribution: context and, 180, *180*
goal-centered expertise, 372
goals: belief attribution and, 177–80, 182–83; complex emotions and, 233; emotions and, 230*t*; interpreting actions in terms of, *177,* 177–78
Golden Rule, 438, 442, 452
Golding, William, 428, *428*
gonads: bipotential, *52*
"goodness of fit," 228, *255,* 257; aptitude-treatment interactions and, 416; child-environment interactions and, 252–55
gorillas: A-not-B error and, 163, *163*; invisible displacements and, 164
gossip, 551, 556
Goths, 554
Graham, Martha, 420*t*
grammatical ability, 262; critical-period effect for, *281*; growth of, 280–81, 301
grandparents: delayed childbearing and, 526; single-parent families and, 530; transmission of human culture and, 633, *633*
grasping, 131; Velcro mittens study and, 127, *128,* 137
grasp reflex, 117, *117*
gravity: infants' understanding of physical world and, 160, *160,* 161
gravity rule, 335
gray matter, 63; changes in, early childhood through puberty and young adulthood, *65*; gene effects studies and, 69; heritabilities of, *70*; schizophrenia and loss of, 618, 619
great apes: gaze following in, 485, *485*; mutual gazing and, 196
Great Britain: attachment styles in, 211, 211*t*
Great Depression: cohort effects related to, 645
Greece (ancient): vitalism in, 334
grooming: mutual, 429, *429*
group changes: in personality, 645–48, *648*
group differences and intelligence tests, 400–407, 423; controversy over, 400; explaining, 402–6; genetic factors and, 403; irrelevancy of, 402–3; over time, 406–7; sociocultural stereotypes and, 404–6; socioeconomic factors and, 403
groups, 545. *see also* social groups
growth cones, 60, *62*
growth hormones: puberty and, 65
growth-inhibiting proteins, 66
"grumpy old men" stereotype, 645, 654
Gua (chimpanzee): Donald Kellogg and, 288, *288*
guanine: DNA double helix and, 36, *36*
guided discovery technique, 413–14
guilt, 233, 434; emergent feelings of, 462; psychopathy and lack of, 610; shame *vs.,* 463, *463*
"guilt culture," 234

habituation, 80, 81, 84, 136; "addition" test and, 168; categorical perception of color and, 85; categorization, essential features and, 175, *175*; idealized example of, *81*; infant indicators of intelligence and, 396–97, *397*; to liquids and solids, *163*; numerical competency and, 166, 167; to smells, 109; sound patterns and, 104; understanding permanence and solidity by 4-month-old infants and, *158,* 158–59
habituation method: infants' visual acuity and, 80
habituation scores in infants: intelligence test scores and, 389
Haidt, Jonathan, 447; moral modules approach of, 443*t,* 444
hair length: heritability of, 397–98
hallucinations: schizophrenia and, 614, 619
handedness: early, genetics of, 124
hands: tracking with, 123
hand washing: compulsive, OCD and, *595*, 596, 597
happiness, 249; social network effects and, 558–59, *560*; uninhibited infants and, 251
Haqqania madrassa (Pakistan), 409–10, i410
hardship: parenting styles and, 509
Harlow, Harry: nonhuman attachments studies of, 218–22, *219, 220, 221*; peer-raised monkey infants study of, 220–22, *221,* 544
harm/care moral module, 443*t,* 444
hawks: silhouette of, 92, *93*
Hayflick limit, 632
Hazda fathers (Tanzania), 204
Hazelwood School District et al. v. Kuhlmeier et al., 570
He, Anna Mae: custody battle over, 188, *188*
Head Start, *408,* 408–9; parenting interventions and, 510, 511
Head-Toes-Knees-Shoulders (HTKS) task, 482
head-to-toe principle, of development, 44, 45
head-turning response, to sounds, 101
hearing, 100–107, 113; aging and, 634; critical-period effects on, 102; legislating early stimulation, 106, *106*; locating sounds, 101, 103; noticing and remembering sounds, 100–101; perceiving complex sound patterns, 104–5, 107; reaching, perception of distance and, 125
heart: aging and, 631
Hebrew language: gendered words in, 292; learning to read in, 307
Heider, Fritz, 494
height: aging and decrease in, 631; heritability of, 68, 397, 400, 403
Hein, Alan, 126
Held, Richard, 126
Helmsley, Leona, 650
helping and hindering cartoon: moral emotions and, 235, *235*
hemispheres: of brain, 57, *57,* 58
Hennessey, Sister Mary Gertrude: science taught by, 416
heritability, 67–68; of brain volumes, 399, *399*; of gray matter, *70*; of height, 68, 397, 400, 403; of intelligence, 397–400; temperament and, 248
heterochronic genes, 40
heteronomous stage: immanent justice and, 434; in Piaget's stages of moral reasoning, 432–34, 432*t, 433*
heterosexual relationships, 552
heterozygous, 37
hidden layers: connectionist approach and, 270
hidden objects: landmarks and, 323
high school: crowds in, 554; students' free speech rights in, 570
high-stakes standardized tests, 422
hindbrain, 58
hippocampus, 19, 60; heritability for volume of, 399, *399*; memory and, 345, 346, 354
Hippocrates, 248
Hispanic Americans: divorce rates among, 532; IQ scores and, 402
Hispanic mothers: mean age for first birth and, *527*
hoarding behavior: OCD and, *595*, 596
Hoffmann, Heinrich, 363, 364
holistic strategies: of learning, 416
homeobox: defined, 50
homeobox genes, 50, *50,* 71
homeodomain proteins, 50
homosexuality: prenatal development, social context and, 53
homosexual romantic patterns, 552
homozygous, 37
homozygous recessive, 37
Hopi infants: motor deprivation in, 119, *120*
hormones: depression and levels of, 605; qualitative changes during puberty and levels of, *11*; sexual differentiation and, *52*
hostile attribution bias: rejected children and, 556, 557

House of Representatives (U.S.): age restrictions for members of, 630
Hox genes, 50, 54
HPA. *see* hypothalamic-pituitary-adrenal axis (HPA)
hues, 84; clustering of, 84; perceiving, 84
human genome, 36–37
Human Genome Project, 400
humans: invisible displacements task and, 163, *163*
Hume, David, 15, *15,* 430

IBQ-R. *see* Infant Behavior Questionnaire-Revised (IBQ-R)
iconic memory, 345
id, 462
identical twins, 43; heritability of intelligence and, 398
identity: operator of, 310
identity *vs.* role confusion: in Erikson's stages of psychosocial development, 649*t,* 650–51
idiographic approach: to study of creativity, 420, 424
Idioma de Signos Nicaraguense (Nicaraguan Sign Language), 284
illusion of explanatory depth, 371
illusions of knowing, 371
imaginary companions, 548–49, *549*
IMHV. *see* intermediate medial hyperstriatum ventrale (IMHV)
imitation: development of birdsong and, 133, 135; early, 131; of facial expressions, 237; by infants, *131,* 131–32; of intended goal, 179, *180*; mirror neurons and, 132, 134; process of, 131–33
immanent justice, 434; across cultures, 436–37
immoral behaviors: poor self-regulation and, 452–53
impersonal moral situation, 446
implantation: of embryo, *46*; of fertilized egg, 44
implantation effect: children as witnesses and, 360–61
implicit cognition, 146
implicit memory, *347,* 348; aging and, 639
"impossible" figures: identifying, *92*
imprinting: action, critical periods, and, 135–36, *136*
impulse control: poor, 453
impulsive behavior: serotonin levels and, 221
impulsivity: genetics, psychopathy and, 613
inanimates: perceivable properties distinguishing animates from, 175–76, 175*t*
incest, 505
incremental theorists, 497
independent variables, 24, 32
India: cows revered in, *430*; lower caste members in, sociocultural stereotypes and, 404; moral thought and collectivist culture in, 442
indiscriminate attachments, 203; disinhibited attachments and, 217
individualist cultures: fundamental attribution error and, 493–94; moral thought and, 441–42; parents in, 575; rights of individuals in, 575; stereotypes, ageism and, 655
industry *vs.* inferiority: in Erikson's stages of psychosocial development, 649*t,* 650
inertia: infants' understanding of physical world and, 160, *160,* 161
infancy, 7; categorization in, *171,* 171–75; differentiating emotions in, 230–35; emotional regulation in, 237–41; reflexes in, *117,* 117–18
Infant Behavior Questionnaire-Revised (IBQ-R), 250
infant cognition, 146
infant cognition field: growth of, 183
infant-directed speech, 267
infant formula: acquired tastes and, *108*
infantile amnesia, 353; cueing hypothesis and, 354–55; memory format change hypothesis and, 354; neural change hypothesis and, 354
infant-parent bonds: ethological approach to, 192–94; learning theory approaches to, 191–92; psychoanalytic approaches to, 190–91; touch and, 197
infants: anxiety and fearfulness in, 592; astigmatism in, *82*; blocking effects and, 141; brightness perception in, *79*; color vision in, 84; comparative considerations in studies of, 162–64; developing bonds between caregivers and, 189–90, 224; experimental research and, 25; eye gazes in, 483, 484; eye tracking in, 172–73, *173*; facial expressions of basic emotions in, *232*; false-belief tasks and, 490; fears in, 142; gaze following in, 485, *485*; imitation by, *131,* 131–32; imitation of facial expressions in newborns of other species, *133*; indicators of intelligence test performance and, 396–97, *397*; interactional partners and, 546; internal working model of, 208; knowledge and understanding in, 157–75, 184; mirror test with, 471, *471*; older, reaching in, *125*; operant conditioning and, 140; overweight, health problems and, 116; preterm (or premature), 47; smiling in, *195,* 195–96; social interactions between, 545, *545*; socially deprived, deficits in, 214–15; spatial knowledge in, 169–71; television watching and, 561, *561*; underpinnings of attachment in, 194–98, 224; understanding permanence and solidity by, *158*; visual acuity in, testing, 79–81, *80*; young, reaching in, *125. see also* newborns
infections: autism and, 591–92; OCD and, 598; prenatal, schizophrenia and, 617–18; preterm births and, 47–48
influenza epidemic (1918): schizophrenia and, 617
informational encapsulation: optical illusions and, 491
information integration theory, 436
ingroup/loyalty moral module, 443*t,* 444
inhibited behaviors: temperament and, 250–52
inhibition: brain development and, 57; false-belief tasks and, 490; frontal lobes and, 480, 481; parental influences and, 253–54; of practiced actions, *157*
inhibitory control, 363; executive functioning and, 361
inimical relationships, 551
initial reading and decoding stage: in reading, 372–73
initiative *vs.* guilt: in Erikson's stages of psychosocial development, 649–50, 649*t*
inputs: development and, 35
inputs to biological system, 36–38; environment, 37; genes, 36–37; interactions between genes and environment, 38
insecure attachment: anxiety and, 593; child abuse and, 537; child effects on, 206–8, *207*; children's social interactions and, 209–10; cortisol, infants's stress responses and, 218; day care and, 212, 213; parent effects on, 203–6
insecure/avoidant attachment: Type A infants and, 202, 203
insecure/resistant attachment: Type C infants and, 202, 203
instant messaging services, 572
institutionalized infants and children: confusing correlation with causation and, 218; cortisol level studies and, 218; critical-period effects and, 222; in Romanian orphanages, *215,* 216–17, *217*; in Russia, study of, 217; Spitz's studies of, 214–15
institutional review board, 25
instrumental conditioning, 139

Kanner, Leo: autism first diagnosed by, 588
Kanner's syndrome, 588
Kanzi (bonobo): lexigrams and, *289,* 289–90
Kapaun, Emil: Medal of Honor awarded to, 427
karyotype, 42, *42*
KE family (England): language gene and, 287
Kellogg, Donald: Gua the chimpanzee and, 288, *288*
Kellogg, Luella, 288
Kellogg, Winthrop, 288
Kenya: intelligence study in, 394, 396; physical punishment in, 460; rural, Flynn effect in, 407, 407*t*
"kewpie doll" configuration: cuteness and, 197
KIAAO319 gene: dyslexia and, 375
"kicking reflex," 118
kidneys: aging and, 631
kindness: in model children, 555
kingfisher: underwater prey and fishing by, 157, *157*
kinsthetic self-concept, 471–72
Kipsigis fathers (Kenya), 204
kittens: active and passive, in Held and Hein study, *126,* 126–27, *127*
Klinefelter syndrome, 43
"knee jerk reflex," 117
knowledge: accessing, metacognition and, 370–72; association-based view of, 15, *15*; domains of, 320–32, 334–36, 340; illusions of knowing, 371; of other, evaluating, 371–72; propensities for learning and, 413; reasoning and thinking about, 366–72, 382; school experiences and awareness about nature of, 372; sociocultural views of development of, 337–39, 340

Kohlberg, Lawrence, 427, 431, 442, 464; alternate version of Milgram's obedience study by, 448; evaluating theory of moral reasoning, 438–40; moral development stages of Gilligan *vs.* those of, 440–41; moral dilemmas and moral reasoning stages of, 444, 445; stages of moral reasoning, 437–38, 438*t*; theory of moral reasoning, 437
Korean children: early childhood amnesia and, 355–56
Korean War, 427
Ku Klux Klan, 479
Kumbo mothers (Cameroon): contingent responding and, 199

Labrador retriever: retrieving by, 15, *16*
LAD. *see* language acquisition device (LAD)
Lambert, Wallace, 296
landmarks: spatial information and, 322, 323; spatial knowledge in infants and, 170, 171
language: as amplifier of thought, 292–94; autism and delayed emergence of, 589; branching direction of, 280; categorical perception of speech and, 105; color perception and, studies of, 85; components of, 262–63; detecting contrasts between, 100–101; domain specificity of, 284–86, 288–90, 301; egocentric use of, 294, 295; emergence of, sensorimotor Stage 6 and, 154; influences of cognitive development on, 294–95; natural, 261; new, inventing, 283–84, *284*; numerical computations and, 326; numerical skills and, 169; parents and use of, 506; phonological awareness and, 374; schizophrenia and difficulties with, 616; social uses of, 298; spatial relative *vs.* spatial absolute, 292–94, *293*; structure and complexity of, 262–63, 300; theory of mind and development of, 492; thought and, 290–95, 301; universal constraints on, 263
language acquisition: age and, 281–84, 301; behaviorist approaches to, 269; child-directed speech, 267–68; correctionist approaches to, 270; developmental patterns in, 263–67; nativist approaches to, 272–73; statistical learning approaches to, 270–72; theories of, 268–73, 300
language acquisition device (LAD), 272
language-based tasks: sex differences and, 401
language development, 260–302; acquiring a first language, 263–68, 300; discovering the meanings of words, 273–80, 300–301; domain specificity of language, 284–86, 288–90, 301; growth of grammar, 280–81, 301; language and communication, 295–99; language and thought, 290–95, 301; structure and complexity of language, 262–63, 300
language gene, 287
language skills: joint attention and, 200
late adulthood, 7, 8. *see also* aging; elderly people
late-emerging biology view, 329, 331
latency period, 546
later development factors: schizophrenia and, 618, *618*
later school age, 7
Latin America: Spitz's social deprivation studies in, 214–15
Latin Americans: awareness of stereotypes, intellectual abilities and, 406
lead poisoning: intelligence test scores and, 407
learned helplessness: depression and, 606
learner characteristics, 416
learning: active, 413–14; aptitude-treatment interactions and, 416–17; brain development and, 64; constraints on, 140–42; domain-specific, 415; educational television and, 562; interactive, 415; metacognitive process and, 413, 415; prepared, 141, *141*
learning disability diagnoses: discrepancies in, 366
learning theories: punishment and, 456, 458–60, 460*t*
learning theory approaches: to infant-parent bonds, 191–92
left-branching language: Japanese as, 280
left hemisphere of brain: babbling and, 264
Leibniz, Gottfried, 15
Leiter Performance Scales, 390
lens (eye), 78, *78*
lesbian parents, 530, 531
letter patterns: associating with sounds, 372, 373, 374
Lewis, David, 435
Lewis and Clark expedition, 429
lexicon, 262
lexigrams: bonobos and, *289,* 289–90
LH. *see* luteinizing hormone (LH)
lies: children's moral judgments about, 434
life course perspective, 630
life expectancy, 8; factors tied to, 632–33. *see also* longevity
lifespan: delayed marriage and impact throughout, 653; dramatic increase in, 652–53; in Sweden, increase in, *653*
lifespan stages: Erikson's approach to, 648–52, 649*t,* 652
lifestyle factor: in psychopathy, decreased brain activation and, *614*
lifestyle stereotyping: stereotyping in media and, 568
light: categories of, and continua, *84*; specializations in eye and, 78, *78*
limb buds, 44
limbic system: risk taking in adolescence and, 65
limb motion: dynamic systems theory and, 120
limbs: constraints on links between eyes and, 123–25
linguistic determinism, 290
linguistic development: day care and, 213; nature/nurture question and, 13
linguistic expressions: developmental roots of, 4
linguistic intelligence: creative geniuses and, 420, 420*t*; Gardner's theory of multiple intelligences and, 393, 393*t*
linguistic relativity, 290, *291,* 292
linguistic rules, 265–67
liquids: properties of, *163*
literacy: bilingualism and, 297; educational television programs and, 563; reduced, television watching and, 564
"Little Albert" studies: classical conditioning demonstrated in, 138–39, *139*
"Little Hans" case, 593
living things: early competence with biological thought about, 332
living world: learning about, *328,* 328–29
lobes: of brain, 57, *57,* 58
local changes, 32; in development, 11–12, *12*
local patterns of development: global patterns of development *vs.*, *305,* 306
local strategies: for learning, 416
Locke, John, 3, 15, *15*
locomotion: measuring spatial knowledge via, 171; surfaces and, 129–30, *130*
logical/mathematical intelligence: creative geniuses and, 420, 420*t*
logical operators: analogical reasoning and, 367
loneliness: social network effects and, 559
longevity, 656; dietary restriction and, 633, 635; factors tied to, 632–33
longitudinal approaches, 32; cross-sectional approaches *vs.*, *27*; developmental differences and, 26; drawbacks with, 26–27; effects of participating in experiments and, 27; tradeoffs with, 29*t*
long-term memory, 345; aging and, 636; explicit *vs.* implicit memory, 346–47, *347*; procedural *vs.* declarative memory, 347–48; semantic memory *vs.* episodic memory, 348–49; types of, 346–49
looking behaviors: interactive, *200,* 200–201
looming objects: dynamic cues and, 86
Lord of the Flies (Golding), 428, *428*
Lorenz, Konrad, 192; on "baby schema," 197, *198*; goslings swimming in pond with, *136*
Lou Gehrig's disease, 66
lung cancer and smoking: correlation between media violence and aggression and, 567, *567*

lungs: aging and, 631
Luria, Alexander: study of emerging Soviet culture by, 575–76
luteinizing hormone (LH): qualitative changes during puberty and, *11*

macaques: A-not-B error and, *163*; epigenetic hypothesis and, 513; imitation in, 132–33, *133*
Machiavellian emotions, 234
macular degeneration, 634
magical thinking: in younger children, 436
Mahatma Gandhi, 420*t*
male analytical tendency: autism and, 590
males: Gilligan's theory of moral development and, 440–41, 440*t*; schizophrenia in, 615; sexual differentiation and, 52; spatial skills and, 400, *401. see also* boys; men
malnutrition: intelligence test scores and, 407
maltreatment of children. *see* child abuse
manic phase: in bipolar disorder, 603–4, 607
Mann, Madeline: extreme premature birth and development of, 34, *34*
Maori (New Zealand): sociocultural stereotypes and, 404
maps, 382; symbolic representations and, 378–79
marijuana: schizophrenia symptoms and, 616
marriage: benefits with delay of, 526; at later age, and impact through lifespan, 653; median age of, over the last century, 525, *525*; same-sex, 530
Mask of Sanity, The (Cleckley), 610
master teachers: science teaching and, 416, *416*
materials: provided by parents, 506
maternal age: at birth of first child, changes over the last century, 525, *525*; Down syndrome and, 591
maternal anxiety during prenatal period: insecure attachment and, 206
maternal depression during pregnancy: quality of parent-child attachment and, 206
maternal reminiscing: and children's autobiographical memories, 357, *357*
mathematical intelligence: Gardner's theory of multiple intelligences and, 393, 393*t*
mathematical knowledge: early, development of, 325
mathematical reasoning, 376–78, 382; development strategies in, 376–77, *377*; emergence of component skills and, 377–78; growth of mathematical skills, 376
mathematical skills: growth of, 376; local development changes and, 12, *12*; video games and, 570
mathematical thought: languages and, 291; themes related to, 326–27
mathematics, 324; gender roles, stereotyping and, 576; parents' gender schemas and courses in, 515; teaching, 376, 378
mathematics-related tasks: Asian-American girls, stereotype threat and, 405, *405*; sex differences and, 400
matrix reasoning: in psychometric tests, *388*
maturational account: of motor development, 118–19
mature organisms: insight into, development as means for, 5
Mayan children: biological properties applied by, 332
Mead, Margaret, 436
mean: standard deviations of, bell curve, 389
media, 544; age portrayed in, 653, *653*; stereotyping in, 568–69
media influences on development, 559–74, 582; Internet communication, 572–74; television, 560–69; video games, 569–72
medications: for childhood psychopathologies, 622–24
medulla, *57,* 58
Meier, Megan, 574
meiosis, *41,* 41–43
memory, 344–58, 380, 381; aging and, 635–37; autobiographical, 348; brain regions and, 345, *345*; circadian rhythms, age and, 642; cognitive reserve and, 641; components of, 345–46; early, neuroanatomical research on, 19; echoic, 345; expertise and, 352–53; explicit, 639; explicit *vs.* implicit, 346–47; iconic, 345; implicit, 639; infantile and early childhood amnesia, 353–56; long-term, 345, 346–49, 636; long-term autobiographical, 356–58; overview of, 344–45; positivity bias in, 645–46, *646*; procedural *vs.* declarative, 347–48; prospective, 638; semantic *vs.* episodic, 348–49; sensory, 345; spatial, 639; strategies for, 349–50; transitive reasoning and, *314,* 314–15; working, 345, 346, 636, 638
memory biases: in anxious children, 594
memory format change hypothesis: infantile amnesia and, 354
memory loss: Alzheimer's disease and, 634
memory tasks: sex differences and, 401
men: aging and muscle mass loss in, 631; bipolar disorder in, 604; depression, stressful life events and, 644; IQ scores of, 400; with Klinefelter syndrome, 43; life expectancy in women *vs.* in, 633; median age of marriage for, over the last century, *525*; memory tasks and, 401; unipolar depression in, 603; violent television programming and aggression in, 565*t*
menopause: osteoporosis in women and, 631
menstruation: anorexia and apprehension over, 601; earlier onset of eating disorders and, 598
mental age score: intelligence quotient and, 387–88
mental retardation: habituation times in children with, 396
mental rotation skills: sex differences in, 400
mental self (James), 469
mercury-contaminated fish: teratogenic effects of, 54–55
mesoderm, 44
meta-analysis: of physical punishment and other variables, 459
metabolism: aging and, 631
metacognition, 350, 381, 382; accessing knowledge and, 370–72; defined, 370
metacognitive process: learning and, 413, 415
metamemory: development of, 350, 352; failure of, in young children, *351*; two facets of, 350
metaphors, 296–97
meta-representation, 491
"Methuselah" worms: breeding, 632
methylation, 39; diet and, 40, *40*; epigenetics and effects of, 513
methylphenidate, 365, 622
Mexican American mothers: mean age of, for first births, 527
mice: epigenetics and families of, *512,* 512–13
microgenetic analysis, 26, 32; of cognitive development, 377, 381
midbrain, 58
middle adulthood, 7, 8
middle childhood: global changes in, 11; latency period in, 546; self-esteem in, 475, 476*t*
middle school children: cliques among, 555; negative stereotypes and, 580–79
midlife crisis: age-related roles and, 653–54
migration: neuron development and, 60
Milgram, Stanley: obedience study of, 448
Miller, Zell, 106
mimicry, 134
"minimal" group affiliations: effects of, 580, *580*
minority groups: sociocultural stereotypes and, 404–6. *see also* ethnicity; race
Minuchin, Salvador, 622; on anorexic families, 601–2
mirror neurons: early imitation and, 132, 134; emotional contagion and, 237; motor empathy and, 455–56
mirror test: self-concept and, *471,* 471–72; variations on, 471–72
miscarriages: DES and, 54
Mister Rogers' Neighborhood, 563

mitochondria: aging, loss of endurance and, 631
mitosis, *41,* 41–43
model children: characteristics of, 555
modeling, 620
modeling theory, 456; moral behaviors and, 460–62
models, 382; “shrinking room” task and, 378–79, *379*; symbolic representations and, 378–79
module: causality and, 166; theory of mind and, 483
Money, John, 473
monitoring: parental, 506
monkeys: addition and subtraction and, 168; clinging in, 196; critical period for developing binocular depth perception in, 88; “cuteness” and, 198; epigenetic hypothesis and, 513; Harlow’s deprivation studies of, 218–22, *219, 220, 221*; neural basis of imitation in, 134; prepared fear in, 243; toy preferences and gender in, 517, *518*
“monkey therapists”: Suomi’s studies of isolated monkeys and, 222, *222*
monozygotic (MZ) twins, 43; aging rates in, 634; anorexia and concordance rate for, 601; autism and concordance rate for, 591; criminality studies of, 453; genetics of early handedness and, 124; heritability of brain volumes in, 399, *399*; heritability of intelligence and, 398; OCD in, 598; schizophrenia and, 616; studies of, *67*; unipolar depression in, 604
Montreal, Canada: bilingualism in, 296
mood disorders, 587
moral behaviors: antisocial and prosocial behavior, 448–52; consistency of, 444–45, 448; development of, 444–45, 448–56, 458–63, 465; modeling theory and, 460–62; social influences on, 456, 458–63; temperament, personality, and, 452–56
moral development, 8, *9*; Freud’s theory of, 462; Gilligan’s theory of, 440–41, 440*t*; learning theory accounts of, 456, 458; Piaget’s theory of, 431–32; social intuitionist model of, 446–47
moral dilemma, 437
moral dumbfounding: defined, 446; as judgment or intuition?, 446–47, *447*
moral emotions, 235, 430
moral intuitions: in impesronal *vs.* personal situations, 446–47
morality, 5; conventions *vs.,* 435; evolutionary and cultural psychology and, 429; multifaceted nature of, 463–64
moralization: process of, 430; smoking and, 430, *431*
moral judgments: Berkeley Free Speech Movement and, 444–45, *445*; cognitions *vs.* emotions as basis for, *431*; cultural variations in, 439; local development changes and, 12, *12*
moral laws: social conventions *vs.,* 435, *435*
moral modules, 443*t,* 444
“moral philosophers”: Kohlberg on children as, 437
moral reasoning: cross-cultural perspectives and, 18; domain-specific, 442–44; evaluating Kohlberg’s theory of, 438–40; evaluating Piaget’s account of, 434–37; justice system and development of, 457, *457*; Kohlberg’s stages of, 437–38, 438*t*; Kohlberg’s theory of, 437; Piaget’s stages of, 432–34, 432*t*; self-regulation and, 481
moral thought: characterizing basis of, 430–31; cultural psychology and approach to, 441–42; debating origins of, 428–29; development of, 427–31, 464–65; personality psychology and approach to, 441; pluralistic approach to, 441–44
Moreno, Jacob L.: sociometry method of, 554
Moro reflex, 117, *117*
morphemes, 264
Morse v. Frederick, 570
mortality rate: of infants in foundling home, 215
morula, 43, *44*
“motherese,” 101
motherhood: age and, *526,* 526–27
mother-infant bond: Freud’s focus on, 190–91
mothers: age at birth of first child, changes over the last century, 525, *525*; child abuse and, 536; as custodial parents, 534; language acquisition and responsiveness of, 268; stereotype threat and attitudes of, 405, *405*; working, child care and, 529–30
motion parallax, *86,* 86–87, 91
motivation, 395; attribution, creativity, and, 497–99
motor deprivation: in Hopi infants, 119, *120*
motor development, 116–44; acceleration of, 137; conditioning, 136, 138–42; dynamic systems theory, 120–22; early imitation and, 131–33; foundations of, 116–22, 143; imprinting, action, and critical periods, 135–36; maturational account and, 118–19; milestones in, 118, *119*; navigating space, 125–31; obesity and, 116; perception and action, 122–23; reaching, 123–25; reflexes in infancy, 117–18; theories of, 118–22
motor empathy, 455–56
motor movement difficulties: schizophrenia and, 616
motor skills: development and refinement of, 122; emerging, *118*; physical constraints and, 121, *121*
motor systems: myelination and, *63*
moving objects: constraints on links between eye and limb and, 123–25, *125*
Mozart, 421
“Mozart Effect”: newborns and, 106, *106*
MRI studies: of schizophrenia, 618–19
Müllerian ducts, *52*
multimodal approaches: to treatment of childhood psychopathology, 624
multiple intelligences: Gardner’s theory of, 393–94, 393*t*
multiple perspectives: teaching children about, 372
multiple sclerosis, 66
multiple viewpoints stage: in reading, 373
multiplication, 376; learning strategies for, 377
multiword utterances, 265, 265*t*
muscle mass: aging and effect on, 631, *631*
muscle strength: nature/nurture question and, 13
music: newborns and, 106, *106*
musical intelligence: creative geniuses and, 420, 420*t*; Gardner’s theory of multiple intelligences and, 393, 393*t*
music performance training: myelination of neuron pathways and, 64
mutual antipathies, 551
mutual exclusivity bias, 277, *277,* 278
mutual grooming, 429, *429*
myelin, 60
myelination, *63*; neuron development and, 60, 62–63
myelin cells: brain damage and, 66
myelin sheath, *59,* 63
MySpace, 572, 574
myth of first 3 years, 181

naive biology, 332
naive physical mechanics, 329
naive physics, 335
naive psychology, 329
Namibia: external referential terms used in, 292
narcissism, 644
narrative skills: development of, 298–99, 346–57; development of episodic and autobiographical memories and, 358*t*
Nash, John, 614, *615*
National Research Council, 329
National Science Foundation, 328
Native-American children: biological knowledge and exposure to nature, 333, *333*
Native-American mothers: mean age of first births and, 527, *527*
nativism, 15–17, 31, 32; Piaget and, 149
nativist approaches: to language acquisition, 272–73

nativists: categorization in infancy and, 172; intelligence tests and, 422; principles about how infants understand and, 161–62
naturalistic intelligence: creative geniuses and, 420*t*; Gardner's theory of multiple intelligences and, 393, 393*t*
naturalistic studies, 581; of television influences on children, 560; on violent television programming and aggression, 564–65
natural language, 261
natural selection: depth perception and, 91; plasticity in perceptual development and, 94; prepared learning and, 141
natural world: children and theories about, 327
nature: biological knowledge and exposure to, 333, *333*
"nature/nurture" debate, 31; empiricists, nativists and, 16, 17; envisioning, *14*; shaping of development and, 12–14
navigating space, 125–31
navigational skills: geometric information and, *322,* 322–23, 324; landmarks and, 322, 323, 324
near-infrared spectroscopy (NIRS): infants' brain function and, 21, *21*; newborn's olfactory cortex, smell and, 109
negative affectivity: in Infant Behavior Questionnaire-Revised, 250
negative cognitions: in anxious children, 594
negative emotions, 231, 232; abused children and, 240–41, *241*; cultural display rules and, 240
negative life events: depression in adolescence and, 606, *607*
negative reinforcement, 140, 456; moral thought and, 430
negative symptoms: of schizophrenia, 614, 615
negative traits: youthful optimism about, 496, 496*t*
negativity bias, 236; emotional contagion and, 237
neglect: effects of, 537
neglected children, 554, 557–58
neglectful/uninvolved parents, 506; characteristics of, 508; effects of, on children's traits and behaviors, 508*t*; interventions designed for, 510
Neisser, Ulric: on five senses of self, 469–70, 470*t*
Nepal: social behaviors and caste in, 575
nerds, 554
nerve cell communication: brain development and, 57
nerve cells, 41; migration and axonal guidance toward target cells, *61*; structure of, *59*
nerve regrowth: myelin and, 66
nervous system: neuroscience perspectives and, 19; rudimentary, 44
Netherlands: attachment styles in, 211, 211*t*; birth order and intelligence study in, *519*; self-referential terms used in, 292
neural change hypothesis: infantile amnesia and, 354
neural dissociations, 285–86, 288; aphasias, 285; specific language impairment, 286, 288; Williams syndrome, 285–86, *286*
neural groove, 45
neural growth: preterm births and, 48
neural plate, 45, 71
neural system: early-emerging, processing eye gaze and, 484, *484*
neural tube, 45, 46, 58, 60
neurodevelopmental model: of schizophrenia, 618, *618*
neurofibrillary tangles: Alzheimer's disease and, 634
neurogenesis, 60; synaptogenesis *vs.,* 61
neuroimaging: twin studies, gene effects and, 69
neuronal complexity: increasing, *62*
neuron development, 60–63; consolidation, 61–62; migration and synaptogenesis, 60–61; myelination, 62–63; proliferation, 60
neurons, 59
neuroscience: perspectives on development, 19, *19,* 31; understanding psychopathology and role of, 625
neuroticism, 643
neurotransmitters, 59; epigenetics, parental care and levels of, 512, *512*
neurulation, 46
newborns: brightness discrimination abilities in, 79; color vision in, 84; extreme premature birth of, 34, *34*; initial state in, *17*; intersensory perception in, 111, *111*; motion parallax in, 87; music and, 106, *106*; perceptual challenges faced by, 3; perceptual development and, 77; preattachment phase in, 193; reflexes in, *117*; sleeping, classical conditioning in, 138, *138. see also* infants
new directions in developmental research: biological knowledge and exposure to nature, 333, *333*; cochlear implants and critical periods for auditory processing, 102; co-rumination, gender, and depression, 608; development of racial and ethnic occupational stereotypes, 578, *579*; effect of parenting on emotion processing in children, 240–41; epigenetics and families, *512,* 512–13; genetics of dyslexia, 375; *g* for emotional intelligence, 395; infant eye-tracking methods, 172; language gene?, 287; mirror neurons and early imitation, 134; moral dumbfounding: judgment or intuition?, 446–47, *447*; near-infrared spectroscopy, 21; new insights into role of the father, 204–5, *205*; repairing brain damage later in life, 66; why we age and why we live as long as we do, 632–33
new languages: inventing, 283–84, *284*
news reports: violent television programming and, 564, *564*
New York Longitudinal Study, 249–50, 252, 257
Nicaraguan home-signers: numbers understood by, 326
Nicaraguan sign language, 284, *284*
NICHD Study of Early Child Care and Youth Development, 212–13
NIRS. *see* near-infrared spectroscopy (NIRS)
nomothetic approach: to study of creativity, 420, 424
noncommunicative condition: A-not-B error and, 156, *156*
nonsolids: infants' understanding of, 162
nonverbal tests: creativity measured with, 417
norepinephrine: alerting and, 360
normal distribution curve: intelligence test scores and, 389, *389*
North America: pervasiveness of intelligence testing in, 400; television viewing studies in, 560
North American children: drawings by, 380; early childhood amnesia and, 356
notochord, 45, 46
novel surfaces study: perception and traversing in, 129, *130*
novelty: wariness of, 251
Nso children (Cameroon): emotional suppression in, 240
nuclear families, 528
nucleus: of nerve cell, *59*
nucleus accumbens: risk taking during adolescence and, 65
number conservation tasks: Donaldson's critique of, 317–19, *319*
numbers: color and, 291; conservation tasks and, 309, *310*; in domains of knowledge, 324–27; intermodal sensing of, 167, *167*; series of, in psychometric tests, *388*; use of, 166–69
Nurse-Family Partnership Program (Elmira, NY), 51
nurturance: parental, 505
nutrigenomics, 39

Obama, Michelle: childhood obesity campaign of, 116
obedience study (Milgram), 448
obesity, 38; childhood, 116; delay in walking and, 121; social network effects and, 558

object collisions: beliefs about, 335
object concept, 149, 150–51; across species, *163,* 163–64; challenges to Piaget's concept of, 155; developing, *151*
object permanence, 149; defined, 158; studies of object solidity and, 158–60
object properties: early understanding of, *162*
objects: beliefs about physical mechanics and, *335,* 335–36; carrying, while crawling, 130, *130*; coordination of secondary circular reactions, 152–53; drawing, 380, *380*; examining A-not-B error relative to, 155–57; eye-tracking evidence in infants and, 172–73, *173*; five principles governing behavior of, 160, *160*; invisible displacement and, 153, *154*; out of sight, thinking about interactions between, *159,* 159–60; persistence principle and, 162, *162*; primary circular reaction and, 150; recognizing, 94–95; recognizing emotions in others relative to, 236–37; secondary circular reactions and, 151–52, *152*; symbolic representation of, sensorimotor Stage 6 and, 154; tertiary circular reactions and, 153, *153*; testing principles pertaining to, *161*; understanding, multiple schemes and, *150*
object solidity: defined, 158; dogs and, 164, *164*; studies of object permanence and, 158–60
object unity: perceiving, 94, *94*
observational studies, 32; challenges in, *22,* 22–23; confidentiality and, 25; limitations with, 23; tradeoffs with, 29*t*
obsessive-compulsive disorder (OCD), 587, 592, 595–98, 644; causal factors in, 597–98; diagnosis of, 596–97; family therapies and, 622; incidence of, 595–96; symptoms cluster in, *595*, 596; types of, 595–96
occipital lobe, *57,* 58
occupations: gender roles and stereotyping about, 576–77
OCD. *see* obsessive-compulsive disorder (OCD)
odors: perception of, 109
Oedipal conflict, 462, 593
offenders: age of, and treatment as adults, 457, *457*
off-label drug usage, 624
Ogbu, John, 404
old age: meaning of, 652–56, 658
olfaction: aging and, 634; taste and, 109
olfactory bulb, 57, *57*
olfactory cortex: smells, newborns and, 109
one-child policy: in China, *522,* 522–23; sex ratios and, 523, *523*
one-word utterances, 264, *264*
online communication: adolescent friendships and, 547
"only children," *522,* 522–23
ontogeny, 49
"ontogeny recapitulates phylogeny," 49; brain development and, 56–57
openness to experience, 643, 644; group changes in, *648*
operant conditioning, 138, 139–40, 620; description of, 139–40
operators, 309
optical acuity: processing ability *vs.,* 83
optical illusions: informational encapsulation and, 491
optic nerve, 78, *78*
optimism: about negative traits, 496, 496*t*; age and, *496,* 496–97; traits and, 496–97, 500
optimization, 656; aging and, 637
optokinetic nystagmus: defined, 81
optokinetic nystagmus method, 81, *82*
orangutans: invisible displacements and, 164
order: agents and, 182, *182,* 183
ordering: OCD and behaviors around, *595*, 596
organ of corti: deafness and damage to, 102
organ systems: aging and, 631
orienting: attention and, 359, 360, 363
orienting information: long-term autobiographical memory and, 357
orienting/regulation (or effortful control): in Infant Behavior Questionnaire-Revised, 250
orphanages: children's cortisol levels in, 218; Romanian, social deprivation and infants and children in, *215,* 216–17, *217*; Russian, large-scale study in, 217
osteoporosis, 656; aging adults with, 631
outcome-based therapy, 624
overextensions: word meanings and, 278, *279*
overjustification effect, 498, 499
overprotectedness: anorexic families and, 601
overregularization, 266
owls: effects of visual distortion on sound localization in, 103, *103*
oxidation: aging and, 632
oxytocin, 196; epigenetics, parental care and, 513; fathering roles, and feedback loops with, 205; touch and levels of, 197

pacifiers: nubby *vs.* smooth, integrating touch and vision with, 110, *110*
Pakistan: Haqqania madrassa in, 409–10, *410*
Pama-Nyungan group: Australian language of, 292
panic disorder, 593
Papua New Guinea: magical thinking in traditional people of, 436
parallel processing, 270
paranoia, 644
parental influences: on temperament, 253–55
parental interactions: with infant with earache, *255*
parental roles: playful *vs.* authoritarian styles and, 205
parent-child bonds, 188
parenting, 505–18, 540–41; across cultures, 508–10; across socioeconomic groups, 509–10; child effects and patterns of, *511,* 511–13, 540; context and, 508–10; effect of, on emotion processing in children, 240–41; effects of sibling relationship quality on, 521; epigenetics and, 512–13, *513*; forms of, 505–6; gender and, 515–18, *516*; genetic effects and, 513–14; improving, interventions for, 510–11; interactionist approach and, *514,* 514–15; older, effects of, 525–26
parenting styles, 506–8; authoritarian parents, 506, 507; authoritative parents, 506, 507–8; cross-cultural studies of, 575; defined, 506; depression in children and, 605; effects of, 508*t*; emotional regulation and, 244–45; links between children's behavior and, *507*; neglectful/uninvolved parents, 506; permissive parents, 506, 507; positive, children's IQ test scores and, 408; types of, 506, 506*t*
parents: changes in age of, 525–27, *526*; children's IQ test scores and education level of, 408; of creative children, 421; developing bonds between infants and, 189–90; development of conscience in children and, 462–63; families and, *505*; family therapies and, 622; insecure attachment and, 203–6; kinds of intelligence nourished by, 396; racial bias in children and, 581; sex differences in intelligence and, 401; shared dispositions between children and, 514; sibling conflicts moderated by, training for, 524, *524*; single, 530; smile of recognition and, 195–96; teaching by, 506. *see also* children; families; fathers; infant-parent bonds; mothers; parenting styles; siblings
parietal lobe, 57, *57*
Parke, Ross: on effectiveness of punishment, 459
Parkinson's disease, 66, 634, 642
Pashto language (Pakistan), 410
passive visual experience: action and, *126,* 126–27, *127*
pastoral-agrarian cultures: fathers in, 204
patellar reflex, 117, *117*
paternal age: incidence of autism and, 591; schizophrenia rates in children and, 616–17
pathological aging, 630, 642

pattern perception: in humans, 91–92; in other species, 92–94
Pavlovian (or classical) conditioning, 138, 141
Pavlov's dogs: classical conditioning and, 138, 139
PCL:YV. *see* Psychopathy Checklist: Youth Version (PCL:YV)
PDD-NOS. *see* pervasive developmental disorder not otherwise specified (PDD-NOS)
Peabody test: vocabulary measures and, 390
Pearl Harbor: Japanese attack on, 544
peer acceptance: causal model of, *556*
peer bonds: among children in concentration camps, *215,* 215–16
peer groups, 544
peer influences: media and, 559
peer nomination technique, 554–55
peer-raised monkey infants: Harlow's studies of, 220–22, *221,* 544
peers, 574, 581; attachment and, 544; interactionist approach to, *514*; levels of affiliation and, 545; ruminative tendencies among, 607; social cognition and, 558
peer victimization: defined, 549–50
pendulum task (Piaget): formal operations and, 312, *312*
Pennsylvania Infant and Family Development Project, 212
Penrose stairs, *92*
Penrose triangle, *92*
perception: action and, 122–31, 143; categorizing ability and, 77
perception biases, 320
perceptual development, 8, *9,* 76–113; central questions about, 77; Gibson's visual cliff studies and, *90,* 90–91; hearing, 100–101, 103–5, 107; intermodal perception, 109–12; plasticity in, 94; smell, 109; taste, 107–8; vision, 78–100
perceptual-motor coordination, *122*
perceptual-motor development, 122
perceptual-motor skills: acquisition of, 126, 131
perceptual narrowing, 97; sound and, 101
performance scale: WISC and, 388, 388*t*
peripheral limb-based constraints, 125
permanence: understanding by 4-month-old infants, *158*
permissive parents, 506, 507; characteristics of, 507; effects of, on children's traits and behaviors, 508*t*
persistence principle: developmental changes and, 162, *162*
personality, 248, 256; birth order influences on, 519–20; linking temperament to development of, 252, *252*; moral behavior and, 452–56; temperament and origins of, 257; temperament-based components of, and early development, 248–49
personality assessment tools, 643
personality disorders, 644
personality psychology: moral thought and contributions from, 441
personality traits: Big Five, 643, 644; changes in individuals, 643–44, 658; constancy of, *643*; contextual perspectives on, 644; group changes and, 645–48, 658; stressful life events and, 644–45
personal moral situation, 446
person-situation interactions: moral thought and, 441
pervasive developmental disorder not otherwise specified (PDD-NOS), 590
pervasive developmental disorders, 588
pharmacological treatments: for childhood psychopathologies, 622–24
phenotype, 38; environment and, 42
phenylalanine, 38
phenylketonuria, 38
phlegm, 248
phobias, 592, 593, 595, 619–20; evolutionary roots of, 242–44; sex differences in, 244
phoneme decoding, 374
phonemes, 262, 264
phonics, 373
phonics approach: in teaching reading, 373–74
phonological awareness, 374, 382; dyslexia and, 375
phonology, 262
phylogeny, 49
physical abuse, 536; effects of, 537
physical attractiveness: facial, *99,* 99–100; popularity and, 555; stereotyping of women and girls in media and, 568
physical causality: module and, 166
physical constraints: motor skills and, 121, *121*
physical development: qualitative *vs.* quantitative change and, 10, *10*
physical mechanics: beliefs about, 335–36
physical punishment: associations between various measures in childhood and adulthood and, 460*t*; social context of, 460
physical self (James), 468
physical world: social world *vs.,* 175–80, 182–83, 184
physics, intuitive, *160*
Piaget, Jean, *147,* 157, 169, 170, 184, 295, 304, 307, 320, 326, 337, 339, 340, 427, 442; alternative explanations for theory and results of, 313–20; animism and, 330, 331; on children's egocentrism and communication, 294; cognitive development theory of, 147–49, 308; concrete operational period, 311; evaluating moral reasoning account of, 434–37; examining the A-not-B error, 155–57; formal operational period, 311–12; key aspects in cognitive development theory of, 154–55; on logical operators, 367; preoperational period, 148, 149*t,* 308–11; scope of work of, 147; sensorimotor period stages of, 149–54; stages of moral reasoning, 432–34, 432*t, 433*; theory of moral development, 431–32; young children with, *308*
Picasso, Pablo, 420*t,* 421
pictorial cues: to depth, types of, 86, 88–89, *89*; emergence of, *91*; misleading, *92*
pictorial depth: sensitivity to, 89, *89*
picture books: prereading stage and, 372
pigeons: prepared learning in, 140, *141*; Skinner boxes and, *139,* 139–40; subtraction and, 168–69
Piraha (Amazon tribe): counting and, 325
PISA. *see* Program for International Student Assessment (PISA)
PKU. *see* phenylketonuria
place error, 153; examining, 155–57
placenta, 43, 44
plants: biological beliefs about, 327
plasticity: in perceptual development, 94; young owl's sound localization system and, 103, *103*
Plato, 15
platoon school, 410–11
play activities: sex differences with, 401, *402*
pleiotropic effects, genes and, 69
pleiotropic gene: three ways to affect behaviors, *71*
plurals: rules for, 266, *266*
pointing: joint-attention and, 200, *200,* 201
politeness mechanisms: across cultures, 298
polygenic traits, 69
P1 electrical waves: abused children and less response in, 240
popular antisocial "tough" children, 555
popular children, 554
popularity: cliques and, 553; perceived *vs.* true, 555; relational aggression and, 556; social adroitness and, 555
popular prosocial "model" children, 555
positive emotionality: arousal levels and, 454
positive emotions, 231, 232
positive-feedback loop: smile of recognition and, 196
positive reinforcement, 140, 456; moral thought and, 430
positive symptoms: of schizophrenia, 614
positivity bias: in older adults, 645–47, *646, 647,* 658
postconventional level of morality: in Kohlberg's stages of moral development, 437, 438, 438*t*

postconventional stage: in Gilligan's theory of moral development, 440, 440*t*
posterior cortex: memory and, 345, *345*
postnatal development, 35
posture: reaching and, 125; visual flow changes and, 129
poverty: attachment styles and, 209, 210; child abuse and, 536; parenting styles and, 509; single-parent families and, 530
poverty of the stimulus argument, 273
practical abilities: successful intelligence and, 394, *394*
pragmatic devices: interpreting, 298
pragmatics, 263
prayer in schools, 412
preattachment phase, 193
preconventional level of morality: in Kohlberg's stages of moral development, 437, 438*t*
preconventional stage: in Gilligan's theory of moral development, 440, 440*t*
preferential looking method, 79
prefrontal cortex, *57,* 58; changes in reward and control circuits and, *67*; memory and, 345, *345,* 346; puberty and, 65; self-regulation and damage to, 481; source monitoring and, 348
pregnancy: alcohol consumption and, 7, 107; delayed childbearing and, 526; diet and, 39–40; intelligence test scores and alcohol consumption during, 407; thalidomide and, 53–54, *54*
prejudice, 581; racial and ethnic occupational stereotypes and, 578, *579*
prelinguistic perception: communication and, 263–64
prelinguistic vocalizations, 264
premature birth: extreme, 34, *34*
premature infants, 47; extreme, *48*
premoral development: in Piaget's stages of moral reasoning, 432, 432*t*
prenatal care: visiting nurses and, 51
prenatal development: changes in sexual characteristics in, 53*t*; milestones of, 45*t*; from 8 weeks to 36 weeks, *47*
prenatal environment: genetic and environmental influences on, 37
prenatal period, 7
preoperational period (Piaget), 148, 149*t,* 308–11, 309*t*
prepared learning, 141, *141*
preparedness: for acquiring certain fears, 242–44; development of disgust and, 244–47, *247*; development of other emotions and, 247
preppies, 554
prereaching, 123
prereading stage, 372
preschool children: analogical reasoning in, 367, *367*; antidepressants prescribed for, 623; beliefs about physical mechanics and, 335–36; counting principles and, 324–25, *325*; expertise as "division of cognitive labor" and, 371; intentions accounted for by, 436; self-esteem in, 475, 476*t*; social groups of, 553; social interactions between, 545
preschool period, 7
preschool years: infant attachment styles and social skills in, 208
pretend play, 545; autism and difficulties with, 589; false-belief tasks and, 490
preterm births, 47–48; interventions for, 48
preverbal infants: sensitivity to others' intentions and goals, 436
Preyer, William, 119
pride, 233
primacy effect: serial position curves and, *349,* 350
primary circular reactions: emergence of, in sensorimotor Stage 2, 150
primary emotions, 230, *231*
primates: A-not-B task and, 163, *163*; clinging in, 196, *197*; imitation in, 132; nonhuman, deprivation studies in, 218–22, *219*; nonhuman, sign language and, 288–89; theory of mind and, 484, 485, *485, 487*
primitive streak, 44–45, 49, 71
principles and parameters approach: growth of grammar and, 280, 281
prison nursery: Spitz's study of infants in, 214, 215
prison populations: incidence of ADHD in, 365
private self, 469–70, *470,* 470*t,* 500
proactive aggression, 550
problem solving, 4; developing strategies for, 376–77; educational television programs and, 562, *562*
procedural competence, 327
procedural fluency: mathematical skills and, 376
procedural memory, 347–48
processing ability: optical acuity *vs.,* 83
processing speeds: aging and, 635
production deficit, 350
Program for International Student Assessment (PISA), 328
prolactin: fathering roles, and feedback loops with, 205
proliferation: neuron development and, 60
propensities for learning, 413
property attribution, 330
prosocial behaviors, 448, *449,* 449–52, 464; altruism and, 452, *452*; empathy and, 454–56; instrumental helping and, 450, *450,* 451, *451*; modeling theory and, 461–62; self-regulation and, 452–53; temperament and, 454
prosocial interactions, 545
prosocial reasoning, 443
prosocial television programs: positive effects of, 562, 563
prosocial video games, 570–71
prosody, 280
prospective memory: aging and, 638
proteins: bases making up genes and, 36; growth-inhibiting, 66; homeodomain, 50
Prozac, 624
pruning: brain development and, 57, 61; deprivation and, 64; frontal lobes and, 65; myth of first 3 years and, 181
psychoactive medications: prescribing to young children, 623
psychoanalytic approaches: to infant-parent bonds, 190–91
psychoanalytic perspectives: on development, 20, *20,* 31
psychoanalytic therapies: in treatment of childhood psychopathologies, 621–22
psychobiomarkers, 632
psychological abuse, 536; effects of, 537
psychological control, 507–8
psychological development, 32; basic questions about, 9–14; global or local?, 11–12; as lifelong process, 630; nature *vs.* nurture and, 12–14; stage-like or continuous?, 9–11; study of, challenges and rewards in, 6; understanding process of, 4–5
psychological development studies: between-subjects design, 30; converging methods, 28; cross-sectional approaches in, *27,* 27–28; experimental studies, 23–26; longitudinal approaches in, 26–27, *27*; observational studies, *22,* 22–23; reliability, 28–29; replicability of, 30; sound, development of, 28–30; validity, 29–30; within-subjects design, 30
psychometric approach, 387–90; correlates of intelligence test scores and, 389–90; emphasis of, 387; interpreting test scores and, 389
psychometric tests, *388*
psychometric theories of intelligence, 390–92; Carroll's three-stratum theory of, 391, *392*; Cattell's theory of fluid and crystallized intelligence, 392; Spearman's theory of general intelligence, 390–91
psychopathology: from developmental perspective, 587
psychopathology in childhood, 586–627; anxiety disorders, 592–98; autism, 588–92; behavioral therapies in treatment of, 619–20; cognitive-behavioral therapy in treatment of, 620–21; conduct disorder: case of psychopathy, 609–14; depression, 603–9; eating disorders, 598–603; evaluating therapies for, 624; family therapies in treatment of, 622; overview of, 587; pharma-

cological treatments for, 622–24; psychoanalytic therapies in treatment of, 621–22; schizophrenia, 614–19; treatment of, 619–24
psychopathy, 609, 626; causal factors in, 612–14; decreased brain activation levels and, *614*; fear processing and, 613, *613*; features of, 610–11; precursors to, 612; symptoms of, 611*t*
Psychopathy Checklist, 612
Psychopathy Checklist: Youth Version (PCL:YV), 611
psychosexual development, 190
psychosis, 614–15, 619
psychosocial conflicts: in Erikson's stages of psychosocial development, 649–52, 649*t*
psychosocial development: Erikson's stages of, 648–52, 649*t,* 658
puberty, 35; anorexia nervosa and, 601; brain development and, 64–65, *65,* 67; increases in hormone levels and qualitative changes during, *11*; qualitative physical change during, 10; rate of depression after, 604; schizophrenia and, 615
public health: television violence as threat to, 567, *567*
public policy: views of intelligence and, 386
punishment: across cultures, 460; behavioral therapies and, 620; of bullies, 550, 551; early and late, 458, *458*; learning theories and, 456, 458–60, 460*t*
punks, 554
pupil (eye), *78*
puppet study: spatial knowledge in infants and, 170
purity/sanctity moral module, 443*t,* 444

Q-CHAT scores: fetal testosterone, autism, and, *590*
qualitative change, 9, 32
qualitative development: quantitative development *vs., 305,* 305–6
quantitative change, 10, 32
Quantitative Checklist for Autism in Toddlers scores. *see* Q-CHAT scores
quantitative development: qualitative development *vs., 305,* 305–6
quantity: brain and estimating differences in, 169
Quine, Willard, 274, 275

race: average age of mother at first birth and, 527, *527*; of children in foster care, *539*; divorce rates and, 532; face perception and, 96–97; parenting interventions and, 510
racial bias: parental behavior and, 581
"racial" differences: intelligence test scores and, controversy over, 402
racial stereotyping: in media, 568; occupational, development of, 578, *579*
radial glial cells, 60
randomized assignment designs, 51
random repetitive movements: in foundling babies *vs.* prison nursery babies, 215; in Harlow's socially deprived monkeys, 219; in institutionalized children *vs.* children in foster homes, 218
rational thought: *Star Trek's* fictional Dr. Spock and, *431*
rats: epigenetics and families of, *512,* 512–13; geometric information and, 323
Ravens Progressive Matrices, 390
reaching, 123–25, 131; brain activity and, in human infants, *132*; constraints on links between eye and limb, 123–25; empiricist view of eye-limb coordination, 123; in older infants, *125*; Velcro mittens study and, 127, *128,* 137; in young infants, *125*
reaction time: aging, speed of processing and, 635, *636*
reactive aggression, 550
reading, 372–75, 382; dyslexia and, 374–75; learning to read, 372–73; nature/nurture question and, 13; proficiency in, 373; stages of, 372–73; teaching, 373–74; television watching and displacement of, 564
"reading faces": autism and difficulties in, 588, *588*
reading to learn stage, 372–73
reasoning: aging and, 638–39; analogical, 366–68, *367,* 382; hypothetico-deductive, 311; mathematical, 376–78, 382; scientific, 368–70, 382; transitive, 308
rebelliousness: birth order influences on, 519
recasting, 267
recency effect, 350
receptors: neuron, 59
recession of 2008: retirement choices in wake of, 656
recessive alleles, 37
reciprocal altruism: in primates, *429*
reciprocal relationships phase, 193
reciprocal teaching, 415
reciprocity: friendships and, 546–47
reconstructing by comparing strategy: for multiplication, 377
reconstructing sums: for addition, 376
referential communication skills: imaginary companions and, 549
referential communication task, 294, *295*
referential detail: long-term autobiographical memory and, 357
reflexes, 155; defined, 117; grasp, 117, *117*; inborn, disappearance of, 117; in infancy, *117,* 117–18; Moro, 117, *117*; in newborns, *117*; patellar, 117, *117*; rooting, 117, *117*; in sensorimotor period, 149–50; stepping, 117, *117,* 118, 121, *121*
reframing: with challenging children, 254–55
"refrigerator mother" scenario: autism and, discrediting of, 591
regulatory cascades, 38, *38*
regulatory sequence: genes and, 36
rehearsal, 349, 350
reinforcement, 19, 269; moral thought and, 430; in platoon schools, 411. *see also* negative reinforcement; positive reinforcement
reinforcement schedules: behavioral therapies and, 620
rejected children, 554, 555–56; social information processing deficits in, 557
relational aggression, 556; cyberbullying and, 574; girls and, 547, *552*
relationships, 545; bully-victim, 549–51, *550*; dating and romantic, *552,* 552–53; developing, 546–53; enemies, 551–52; friendships, 546–48, *547*; handling, 395; with imaginary companions, 548–49, *549*; inimical, 551; relational aggression, 551–52, *552*
relativism, 372
reliability, 32; forms of, 28–29
religious beliefs: cross-cultural perspectives and, 18
religious/blasphemous thoughts: unwanted, OCD and, *595*, 596
religious values: schools as vehicles of, 412
remarriage: blended families and, *535,* 535–36
remembering. *see* memory
repeated addition strategy: for multiplication, 377
repeating behaviors: OCD and, *595*, 596
repetition: in platoon schools, 411
replicability, 30, 32
resilience: self-regulation and, 453
resistance training: muscle atrophy reduced with, 631
resource theory: birth order effect on intelligence and, 518
respiratory illness: insecure attachment and children with, 207
response modification: emotional regulation and, 238, 239–41, *242*
retina, 78, *78*
retinal images: growth of eye and, 82–83, *83*
retinoids: as teratogens, 54
retirement: longevity and, 656; mandatory, abolition of, 655
retrieval, 345
retrieving a known product strategy: for multiplication, 377
retrieving sums: for addition, 377
reversibility: operator of, 309–10
reward and control circuits: changes in, *67*
rewards: behavioral therapies and, 620; effects of, on intrinsic motivation, *498,* 497–99

rhesus monkeys: theory of mind and, 484, 485, *485*
riddle of reference, *274,* 274–75
right-branching language: English as, 280
rigidity: anorexic families and, 601
risk taking: adolescence and social nature of, 65; adolescents and, 64; younger adults and, 645
Risperdal, 624
risperidone, 624
Ritalin, 365, 622, 623
robotic surgical techniques: video game skills and, 569
role-playing games, 572
rolling car study (Baillargeon), 159, *159,* 161, 164
rolling over, 118
Romanian orphanages: children's cortisol levels studied in, 218; critical-period effects and gray matter cortical volumes in children in, 223; social deprivation and infants and children in, *215,* 216–17, *217*
romantic relationships, 552–53; in adolescence, 544; among teenagers, rise in, 552, *552*; conflicts in, 552; defined, 552; older adolescents and, 553
rooting reflex, 117, *117*
Rosch, Eleanor, 316, 317
rough-and-tumble play: in boys' friendships, 547
Rousseau, Henri, *328*
Rousseau, Jean-Jacques, 410, 428
Rubinstein, Arthur: selection, optimization and compensation used by, 638, *638*
rumination: depression and, 607, *607*
ruminative cognitions, 587
rumors, 551
rural youth: developing biological thought in, 333, *333*
Russia: study of institutionalized children in, 217
Russian Revolution: Vygotsky's support for, 338

sadness, 231, 233, 249; facial expression in infant, *232*; goal and action related to, 230, 230*t*
"Sally-Anne tasks," 487, *489*
salty taste, 107
same-sex couples: stigma and, 552
same-sex parents, 530–32, *532*; families with, 505
sampling bias: refrigerator mother theory and, 591
San Francisco Waldorf School, 410, *410*
Sapir, Edward, 290
Sapir-Whorf hypothesis, 290–91, *291,* 292
SAT: ADHD and special accommodations for, 364, 366
SAT scores, 390; delay in gratification and correlation with, 480; stereotype threat and, 405
Savage-Rumbaugh, Sue: bonobos and lexigram studies of, 289, *289*
scaffolding, *338,* 338–39, 340, 477
schadenfrude, 456
schemes, 147, 148, 155, 308; modifications in, related to reflexes, 150; multiple, understanding objects and, *150*; primary circular reaction and, 150; secondary, integration of, *152*; secondary circular reaction and, 151
schizophrenia, 587, 614–19, 626; ADHD and, 364; affective blunting and, 616; causal factors in, 616–18; cross-cultural view of, 618; diagnosis of bipolar disorder as distinct from, 609; early-onset, 619; emergence of, in young adulthood, 615, *615*; features of, 614–16; genetic basis of, 616–17; in Germain quadruplets, 617, 618; infection theory and, 617–18; lifetime prevalence of, 615; neurodevelopmental model of, 618, *618*
"schizovirus," 617
school-age children: friendships between, 546–47
school performance: predicting, intelligence tests and, 390
school readiness: cultural variation and, 481–82
schools, 409–17, 423; bullying in, 550; characterizing, 409–11; computers and e-learning in, *418,* 418–19; as cultural institutions, 411–12; "learner characteristics" and, 422; local subcultures and, 412; as socializing agents, 411, *411*; thought and, 412–17; as vehicles of values, 412
school shootings: victims of bullying and, 550
science: intuitive, Sputnik and, 328–29; teaching children how to think about, *416*
science courses: parents' gender schemas and, 515
science education: Sputnik and, 328–29
scientific method: agents and order, 182, *182*; diet and methylation, 40, *40*; direct *versus* inquiry-based methods of instruction, 414, *414*; early motivation to learn about kinds over individuals, 318, *318*; early use of syntax to guide learning new words, 276, *276*; gaze following in human infants and great apes, 485, *485*; genetics of early handedness, 124, *124*; inferring actions from emotions, 238, *238*; instrumental helping in toddlers, 450, *450*; internal working models and attachment styles, 209, *209*; intersensory perception at birth, 111, *111*; maternal reminiscing and children's autobiographical memories, 357, *357*; "minimal" group affiliations, 580, *580*; positivity bias in older adults, 647, *647*; psychopathy and fear processing, 613; training parents to moderate sibling conflicts, 524, *524*
scientific model, 312
scientific reasoning, 368–70, 382
"scientific thinking skills": emergence of, 312
Scribner, Sylvia, 411
search engines: learning and, 419
secondary circular reactions: appearance of, in sensorimotor Stage 2, 151–52, *152*; coordination of, in sensorimotor Stage 4, 152–53
secondary schemes: integration of, *152*
second language acquisition: critical periods and, 281
secure attachment: children's social interactions and, 208; cortisol, infants's stress responses and, 218; Type B infants and, 202, 203
secure base, 193
security motivational system: obsessive-compulsive disorder and, 597
seeing: walking and, 127–31
selection, 656; aging and, 638
self-awareness, 395
self-concept, 501; gender identity and, 472–74, *473*; kinesthetic, 471–72; mirror test and, *471,* 471–72; self-esteem *vs.,* 474–75
self-conscious emotions, 233
self-determination, 499, 500
self-disclosure: developmental changes in, 547–48
self-efficacy, *476,* 476–77, 500; "contagiousness" of, 477; defined, 476; modeling approaches and, 620
self-esteem, 474–75, 500; anorexia nervosa and, 598–99; bulimia nervosa and, 599*t*; in bullies, 550; defined, 474; developmental changes in, *475,* 475–76, 476*t*; potential drawbacks of, 478–79; self-concept *vs.,* 474–75; self-efficacy and, 476
self-interest, 5
self-knowledge: developmental roots of, 4
self-regulation, 477–82, 500, 501; brain maturation and development of, 480–81; contextual influences on, 481–82; cross-cultural differences in, 482, *482*; damage in frontal lobes and difficulties in, 480, *480*; defined, 477; Head-Toes-Knees-Shoulders (HTKS) task and, 482; lack of, *453*; mirror effect and, 481; moral behavior and, 452–54; resilience and, 453
self-representation, 501; toddlers and, 472
self-worth: developing sense of, 474–77, 501

semantic development, 273; linking features with meanings and, 278–79
semantic memory, 348; aging and, 639
semantics, 262
Senate (U.S.): age restrictions for members of, 630
senior citizens: media portrayal of, 653, *653. see also* aging; elderly people
senses of self, 468–70, 499–500; conceptual self, 470, 470*t*; defined, 468; ecological self, 469, *469,* 470*t,* 472; extended self, 469, 470*t*; interpersonal self, 469, *469,* 470*t*; long-term episodic memories and, 357; private self, 469–70, *470,* 470*t*
sensitive periods: for calibrating sound localization system, 103
sensorimotor period (Piaget), 148, 149–54, 149*t,* 154*t,* 308, 309*t*; coordination of secondary circular reactions: stage 4 (9 to 12 months), 152–53, 154*t*; invention of new means through mental combinations: stage 6 (18 months to 2 years), 154, 154*t*; primary circular reactions: stage 2 (1 to 4 months), 150–51, 154*t*; secondary circular reactions: stage 3 (4 to 9 months), 151–52, 154*t*; tertiary circular reactions: stage 5 (12 to 18 months), 153, 154*t*; use of reflexes: stage 1 (birth to 1 month), 149–50, 154*t*
sensorimotor reflexes, 308
sensory memory, 345, *345*
sensory systems: myelination and, *63*
sentences: novel, 262
separation anxiety, 190, 593
separation distress, 190, *190,* 593
separation of religion and state, 412
sequencing: of development, 71
serial position curves: age and, 349, *349*
seriation: preoperational stage and, 310
seriation tasks (Piaget): alternative explanations of, *314,* 314–15
serotonin: epigenetics, parental care and levels of, 512, *512,* 513; peer-raised monkey infants and levels of, 220–21
SES. *see* socioeconomic status (SES)
Sesame Street, 563
sex chromosomes, 37, 42; extra, or missing, 43
sex differences: biological, emergence of, *52*; in experiences with toys, 401, *402*; intelligence tests and, 400–402
sex ratios: aging and, *633*; one-child policy in China and, 523, *523*
sex-stereotyped behaviors: prenatal testosterone levels and, 516, 517, *517*
sex-stereotyped toys, 515, 516
sexual abuse, 536; effects of, 537
sexual characteristics: prenatal development and changes in, 53*t*
sexual differentiation, 52–53
sexual intercourse: fertilization and, 43, *43*
sexual orientation: prenatal development, social context and, 53; romantic relationships and, 552
sexual reassignment, 473
sexual thoughts: unwanted, OCD and, *595,* 596
shame, 233, 430; emergent feelings of, 462; guilt *vs.,* 463, *463*; psychopathy and lack of, 610
“shame culture,” 234
shape bias, 275
shaping, 139
sharing, 429, 545; cross-cultural differences in, 575; development of, 451–52; empathy and, 455; fostering, prosocial television programs and, 563
sheepdogs: herding by, 15, *16*
short-term memory, 346
“shrinking room” task: models and, 378–79, *379*
Shweder, Richard, 429
shyness, 234, 251, 545; child effects on parenting and, 511–12; heritability of, 398; person-situation interactions and, 441; shared disposition theory and, 514
sibling differentiation, 519, 520
siblings: autism and, 589; birth order effects on, 518–20; differences between, *504,* 504–5; family dynamics and, 518–21, 524–25, 541; foster care and, 525, 539; gender socialization and, 517–18; jealousy and conflict between, 520–21; “only children” in China without, *522,* 522–23; relationships within family, 521, 525; social understanding and, 521; training parents to moderate conflicts between, 524, *524. see also* families
sign language: nonhuman primates and, 288–89. *see also* American Sign Language (ASL)
simple reaction time, 635
single-parent families, 505; increase in, 526; studies of, 530
situational factors, 493, 494; emotional regulation and, 238
situation modification, 239
situation selection: emotional regulation and, 239, 240
skin cancer, 38
Skinner, B. F., 139, 269, 620
Skinner boxes: pigeons and, *139,* 139–40
skin wrinkling: aging and, 631
sleep disorders: aging and, 634
SLI. *see* specific language impairment (SLI)
slow to warm up babies: in New York Longitudinal Study, 249
slow-twitch muscles: aging and decline in, 631
“Smarties task,” 487, *488*
smartphones, 419, 569
smell, 109, 113; taste and, 109
smiles, 193; attachment complex and, 194; eliciting, stimuli involved in, *195,* 195–96; joy and, 247; variations in, 231
smoking: moralization and, 430, *431*; preterm births and, 48; social network effects and, 558
smoking and lung cancer: correlation between media violence and aggression and, 567, *567*
snakes: learning to associate with fear, *246*; phobias related to, 242–44, *243*; threat detection and, 243–44, *246*
Snell’s law, *157*
snow example: linguistic relativity and, 290
sociability, 248
social adroitness: of popular children, 555
social affiliations: developmental changes in, 558, 559*t*
social agents: goals attributed to, 179; imitation of intended goal and, 179, *180*; observable properties of, 175–76, 175*t,* 177; older, preverbal infants and, 182, 183
social aggression, 454
social anxiety disorder, 592, 593, *593*
social bonds: infants and formation of, 194; between parents and children, 188
social capital effects: birth order and, 520
social cognition: peer relations and, 558
social collaborations, 4
social comparison, 553
social comparison skills: self-esteem and, 475
social context: morality and, 441–42
social contingency: action at a distance and, *176,* 176–77; perceiving, *177*
social conventions, 435
social deprivation, 214–18, 225; attachment and, 189; children in concentration camps and, 215; critical-period effects and, 222–23; deficits in socially deprived infants, 214–15; in humans, 214–18; in nonhuman primates, studies of, 218–22; Romanian orphanages and, *215,* 216–17, *217*; untangling causation in, 215–18
social development, 8–9, *9*
social dominance: cognition and, 484, *485*; sexual differentiation and, 52–53
social-emotional states: testosterone levels and, 590–91
social factors: depression and, 605
social groups, 553–58; cliques and crowds, 553–54; dominance hierarchies in, 553; in early adolescence, *554*; sociometric status and social interaction, 554–58
social influences on moral behavior, 456–63; modeling theory and moral behaviors, 460–62; parent-child interactions and development of conscience, 462–63; punishment and learning theories, 456, 458–60

social information processing model: of attributions in children, *556*; steps in, 556–57
social intelligence, 395; socially anxious children and, 594–95
social interactions: attachment styles and, 208–10; bases of, 199–201; changing nature of, 545–46; contingent responding and, 199; early, 545, *545*; joint attention and gaze following in, 200–201; negative, 545, *546*; social referencing and, 199–200
social intuitionist model, 446–47
socialization: in schools, 411, *411*; sibling relationships and, 520–21, 524–25
social learning, 620
social learning perspective: cycle of abuse and, 537
social learning theory: moral behaviors and, 460
socially anxious children: cognitive interpretations by, 594
social network effects, 558–59; happiness and, 558–59, *560*; obesity and, 558
social networking, 419, 572, 581; free speech and, 571
social policy: development and, 6. *see also* development and social policy
social reasoning skills: theory of mind and, 484–85, 487
social referencing, 199–200, 236
social responsiveness: schizophrenia and deficits in, 616
social sharing of memories, 357
social skills: bonds and, 190
social status: socialization across cultures and, 575
social stresses: depression and, 605
social support: healthy aging and, 631
social world: physical world *vs.,* 175–80, 182–83, 184
sociocultural stereotypes: group differences, intelligence tests and, 404–6
sociocultural view of development, 337–39, 340
sociodramatic play: in individualist cultures, 575
socioeconomic factors: group differences, intelligence tests and, 403
socioeconomic groups: parenting across, 509–10
socioeconomic status (SES): anorexia nervosa and, 599; eating disorders and, 598; extra time on high-stakes tests and, 366; family size and, 528; higher, authoritative parenting style and, 509; Internet use patterns and, 573*t*; schools and, 410; siblings' development and, 504, 520; single-parent families and, 530
sociometric popularity: perceived popularity *vs.,* 556
sociometric status: social interaction and, 554–58
sociometry, 554
sociopathy, 609
soft constraints: birdsong and guidance by, 133
solidity, 335; cross-species awareness of, 163–64; 4-month-old infants and understanding of, *158*; infants' understanding of physical world and, 160, *160,* 161, 162; studies of, *158,* 158–59
solids: properties of, *163*
somatic concerns: excessive, OCD and, *595*, 596
somatosensory cortex, *57,* 58
songbirds: critical period in, 135; imitation theme and, 133, 135
sound: categorical perception of, 104–5; heard by fetus in utero, 100; locating, 101, 103; noticing and remembering, 100–101
sound patterns: complex, perceiving, 104–5, 107; recurring, learning abstract rules and, 271, *271*
sound-vision relationship, 110, 111, *112*
source monitoring, 348; aging and failures in, 638
sour taste, 107; facial response to, 107
southeastern United States: culture of honor in, *574,* 574–75
South Korea: gender and educational investment in, 520
Soviet Union, 338; Luria's investigations of rural peasants in, 575–76; Sputnik launched by, 328, *328*
Spain: childhood obesity in, 116
Spanish language: bilingual education in U.S., 297; masculine and feminine terms in, 292
spatial cognition: hippocampal volume and, 399
spatial contiguity, 165
spatial/geometric visualization ability, 378
spatial intelligence: creative geniuses and, 420, 420*t*; Gardner's theory of multiple intelligences and, 393, 393*t*
spatial knowledge: in infants, 169–71
spatial memory: aging and, 639
spatial navigation, 125–31; active *vs.* passive visual experience and action, *126,* 126–27, *127, 128*; walking and seeing, 127–31
spatial relations: in domains of knowledge, 321–24; geometric information, *322,* 322–23; landmarks, 322, 323, 324
spatial relative *vs.* spatial absolute languages, 292–93, *293*
spatial representation, 169
spatial skills: sex differences in, 400, *401*
Spearman, Charles: general intelligence theory of, 390–91
species specificity in language acquisition, 288–90; bonobos and joint attention, *289,* 289–90; chimp raised as child, 288, *288*; nonhuman primates and sign language, 288–89
specific bonds, 189, 190
specific language impairment (SLI), 286; counting-out-load routines and, 325
speech: categorical perception of, *104,* 104–5; child-directed, 101, 267–68, *268,* 269; telegraphic, 265
speech perception: developmental patterns in, 105
speed-of-processing tasks: exercise, aging and, *640*
Spelke, Elizabeth, 160, 163, 164
sperm cell mutations: incidence of autism and, 591
sperm cells, 41, 42
spiders: fear of, 243–44
spina bifida, 46
spinal cord, *57,* 58; initial formation of, 46; myelination and, 63
spirituality, 429
spiritual self (James), 469
Spitz, René: social deprivation studies of, 214–15
Sputnik, *328*; intuitive science and, 328–29
squirrels: perceptual-motor coordination in, 122, *122*
St. Petersburg-USA Orphanage Research Team, 217
stages of development, 10, 32
stages of life: Erikson's approach to, 648–52, 649*t,* 652, 658
stage theorist: Piaget as, 148
stair climbing ability: Gesell's twin studies on, 119, *120,* 137
standard deviation: normal distribution curve and, 389, *389*
Stanford-Binet Intelligence Scales, 388
starlings: birdsong in, 133
Star Trek, 431
statistical learning approaches: to language acquisition, 270–72
stealing: moral laws and prohibitions against, *435*
Steele, Claude, 404, 405
stem cells, 66
stepchildren, *535,* 535–36
stepfamilies, *535,* 535–36
stepmothers: sex differences and relationships with, 536
stepparents, *535,* 535–36
stepping reflex, 117, *117,* 118; physical constraints, motor skills and, 121, *121*
stereopsis, 87, 88
stereotyped movements: autism and, 589
stereotypes, 581; ageism and, *654,* 654–55; cultural variation in ageism and, *655,* 655–56; gender roles and, 576–79; in

media, 568–69; sociocultural, IQ scores and, 404–6
stereotype threat, 404–6; attitudes of mothers toward, 405, *405*; reducing, 405
stigma: same-sex couples and, 552
stigmatized groups: stereotype threat made salient and, 406, *406*
still face: emotional regulation and dealing with, 245; infant's reaction to, 199, *199*
stimulants: increased use of, in children, *622,* 624
stoners, 554
storage, 345
"Story of Fidgety Philip, The" (Hoffmann), 364, *364*
"story problems": mathematical skills and, 376
story telling, 299; schooling and, 413
straight-down rule, 335, *335*
Strange Situation, 206, 210, 211; attachment style across cultures as measured by, 211, 211*t,* 214; attentional deployment and, 239; cross-cultural comparisons and limitations of, 214; day care studies and, 212; studying attachment styles in, *202,* 202–3
Stravinsky, Igor, 420*t*
stress: attachments and, 217–18; depression in girls and, 606; fetus's exposure to testosterone and, 53; *5-HTT* gene and kinds of effects with, 221; gene regulation and, 69; OCD and, 598; parental, methylation effects and, 513; preterm births and, 48; schizophrenia and, 615, 618; telomeres and, 632; unipolar depression and, 604–5; work-related, parenting styles and, 509
stressful life events: personality traits and, 644–45
striatum, 65
structural sequence, 36
structures: differentiation of, 39–40
student collaborations: active learning and, 413, 414
substance: beliefs about, 336
substance abuse: child abuse and, 537; family therapies and, 622; rejected children and, 557
subtraction, 376; infants and simple form of, 167–68; monkeys and notion of, 168
successful aging, 630, 631, 634, 642; selection, optimization, compensation, and, 637–38, *638*
successful intelligence: Sternberg's theory of, 394, *394,* 396
successive differentiation, 46
sucking response: operant conditioning and, 140
suckling reflexes, 117; in sensorimotor period, 149
sudden infant death syndrome, 197
sugar: infant preference for, 107
suicide: antidepressants and, 623; cyberbullying and, 574
Sullivan, Harry Stack: on chums, 547, *547*
Sulloway, Frank: birth order study by, 519, 520
Suomi, Stephen: rehabilitation studies of, *222*, *222*
superego, 462
Supreme Court (U.S.): free speech for minors and, 570, 571
surgency/extroversion: in Infant Behavior Questionnaire-Revised, 250
surgical techniques: robotic, video game skills and, 569
surprise, 249; facial expression in infant, *232*
swamp sparrows: development of birdsong in, 133
Sweden: attachment styles in, 211, 211*t*; childhood obesity in, 116; conversational norms in, 298; divorce rate in, *533*; increased lifespan in, *653*
sweet liquids: facial response to, 107
sweet taste, 107
symbolic representations, 378–80, 382; in children's drawings, 379–80; maps and models, 378–79
symbols: delay of gratification and effects of, 479; simple, preoperational period and, 308; writing, 307
symmetry behaviors: OCD and, *595*, 596
synapses, 59
synaptic pruning, 61
synaptogenesis: neuron development and, 61
syntactic boot-strapping, 277
syntax, 262, 280, 281; learning new words and early use of, 276, *276*

tablet computers, 419, 569
tabula rasa, 3, 139
tactile stimulation: physiological needs and, in Harlow's studies of infant monkeys, 218–20, *219, 220*
tadpoles: qualitative *vs.* quantitative developmental change and, 10, *10*
Taking to School, 329
Tamang caste, Nepal: social behaviors and, 575
tantrums, 245, 514
Taoka, Rahan, 544
tape recording: observational studies and, 23
taste, 107–8, *108,* 113; acquired, *108*; aging and, 634; facial expressions and, 107, *108*; infant preference for sweet substances, 107; smell and, 109
taxonomic assumptions, 276
taxonomic organization, 327
teaching: children how to think about science, *416*; cognitive science ideas and, 413, 415–16; mathematics, 376, 378; by parents, 506; reading, 373–74; reciprocal, 415
technological culture: Flynn effect and, 407
technology: observational studies and, 23; stereotypes, ageism and, 655
technology-related careers: mathematical skills and, 378
teenage dating, 546
teenage girls: eating disorders in, 598
teenage mothers: developmental factors and, 526–27; schooling for, *527*
teenagers: romantic relationships and, 552, *552*
teen pregnancy: rates of, *527*
telegraphic speech, 265
telegraph operator speed: aging and, 635
telencephalon, 58
television, 544, 560–69, 574; age and changes in television watching, *561,* 561–62; experimental *vs.* naturalistic studies and, 560; introduction in rural Fiji, increase in eating disorders and, 569, *569,* 599; negative cognitive effects of, 563–64; negative social effects of, 564–67; pervasiveness of television watching, 560–61; positive effects of, 562–63; responding to violence on, 567–68; stereotyping and, 568–69; V-chip technology and, 567–68, *568*; viewing throughout the world, 560, *561*
telomerase, 632
telomeres: aging and, 632
temperament, 228, 256; ADHD and, 364; attachment style and, 207; determining differences in, 249–52; in dog breeds, 251, *251*; emergence of, 247; linking to personality development, 252, *252*; modern approaches in study of, 250–52; moral behavior and, 452–56; origins of personality and, 257; parental influences on, 253–55; parenting style and, 512–13; sibling jealousy and, 521
temperament-based components: of personality and early development, 248–49
temporal contiguity, 165
temporal lobes, 57, *57,* 345
teratogens, 54; development and, 54–55, 55*t*
Terezin, Czechoslovakia: close peer bonds among children in concentration camp in, 215–16, *216*
terrier: temperament in, *251*
terry-cloth mother: Harlow's studies of infant monkeys bonding with, *219,* 219–20
tertiary circular reactions: appearance of, in sensorimotor Stage 5, 153
testosterone: empathy-related brain regions and levels of, 590–91; fathering and levels of, 204; fetal, subsequent autism and, 590, *590*; sex-stereotyped behaviors and prenatal levels of, 516, 517, *517*; sexual differentiation and, *52*; stress and fetal exposure to, 53

test-retest reliability, 28–29
texting, 419, 581; adolescent friendships and, 547
texture gradients, 88, *89*
Thailand: physical punishment studied in, 460
thalamus: alerting and, 360
thalidomide, 53–54, *54*
Thelen, Esther, 118, 121, 137
theory of mind, 468; autism and, *491,* 491–92; beyond false beliefs and, 492–93; comparative perspectives on, 484–85, 487; developing, 482–93, 501; developmental patterns in levels of affiliation and, 558; in dogs?, 486, *486*; early aspects of, 483–84; full-fledged, infants and development of, 484; humor and, 492, *492*; mature, 483; understanding false beliefs, 487–90
theory of mind module (TOMM), 490–92
theory of mind skills: friendships and, 546–47; siblings and, 521
thinness: idealization of, eating disorders and, 599–600
Thomas, Alexander, 249, 250, 252
Thorndike, Edward: social intelligence tests and, 395
thought: influence of language on, 290–95, 301; language as amplifier of, 292–94; schools and, 412–17
threat detection, 243–44, *246*
three mountains task (Piaget), *321,* 321–22
three-stratum theory of intelligence (Carroll), 391, *392*
thrifty phenotype hypothesis, 34
thumb-sucking, 239, *242*; children of depressed mothers and, 245
thymine: DNA double helix and, 36, *36*
Tibet: cheating by schoolchildren in, *449*
time management: parents and, 506
timing and sequencing: of developmental events, 38, 40–41, 71
Tinbergen, Niko, 192
Tinker v. Des Moines Independent Community School District, 570
toddlers: ADHD and, 364; counting by, 325; enrichment programs for, 137; friendships between, 546; infant attachment styles and social skills in, 208; instrumental helping in, 450, *450,* 451, *451*; perceptual-motor coordination in, 122, *122*; self-representation and, 472; social interactions between, 545; television watching by, 562; with/without autism, visual fixations by, 588, *588*
touch: aging and sensitivity to, 634; attachment complex and, 196–97; integrating vision and, 110, *110*
tough children: characteristics of, 555
toxoplasmosis, 617
toys: cross-cultural study of children's interactions with, 575; gender and preferences for, in vervet monkeys, 517, *518*; gender-atypical, congenital adrenal hyperplasia in girls and, 516–17; sex differences in experiences with, 401, *402*; sex-stereotyped, 515, 516, 576
Trabasso, Tom, 314
"tracking scheme": objects and, 151
traffic fatalities: age groups and, 645, *645*
trait approaches, 248
trait-based reasoning, 494–95; defined, 494; evaluative reasoning *vs., 494*
traits: heritability of, *67*–68, 397–98; optimism and, 496–97, 500; polygenic, 69
trajectories: beliefs about, 335
transitive reasoning (or transitive reference), 308; memory and, *314,* 314–15
transitive reasoning skills: schooling and, 413
transitivity, 315
treatment of childhood psychopathologies, 619–24, 626; behavioral therapies, 619–20; cognitive-behavioral therapy, 620–21; evaluating therapies for, 624; family therapies, 622; pharmacological treatments, 622–24; psychoanalytic therapies, 621–22
trisomy 21: Down syndrome and, 42, *42*
trophoblast, 43
Tropical Forest with Apes and Snakes (Rousseau), *328*
trust *vs.* mistrust stage: in Erikson's stages of psychosocial development, 649, 649*t*
Turkey: collectivist/individualist contrast in, 576; Kohlberg's model and evaluating moral development in, 439
Turner syndrome, 43
turn-taking: in communication, 298, 299
twin studies: on aging, 634; on anorexia nervosa, 601; on anxiety disorders, 595; attachment style and, 207; on autism, 591; on criminality, 453; dyslexia and, 375; gene effects and, 69; genetics of early handedness in, 124; heritability of brain volumes in, 399, *399*; heritability of intelligence in, 398; on obsessive-compulsive disorder, 598; on schizophrenia, 616; on stair climbing ability, 119, *120,* 137; on unipolar depression, 604
two-word utterances: early, 265*t*
type AB blood, 37
type A blood, 37
Type A infants: cross-cultural differences and, 211, 211*t*; insecure/avoidant attachment and, 202, 203
type B blood, 37
Type B infants: cross-cultural differences and, 211*t*; secure attachment and, 202, 203; social abilities and, 208
Type C infants, 207; cross-cultural differences and, 211, 211*t*; insecure/resistant attachment and, 202, 203
Type D infants: disorganized attachment and, 203
type O blood, 37
typing speed: aging and, 637
Tzeltal language (Mexico): encoding directions in, 292, *293*

UCR. *see* unconditioned response (UCR)
UCS. *see* unconditioned stimulus (UCS)
Uganda: attachment style studies in, 210
uncertainty: children and sense of, 372
unconditioned response (UCR), 138, 139
unconditioned stimulus (UCS), 138, 139
unconscious, 20
underarousal: adult criminality and, 454
underextensions: word meanings and, 278, *279*
understanding in infants: guiding principles for, 160–62
unexpected contents tasks, 487
uniformity: diversity out of, 49–50
uninhibited behaviors: temperament and, 250–52
unipolar depression, 603, 604–7; biological causes of, 604–5; bipolar disorder *vs.,* 603*t*; cognitive causes of, 605–7; social causes of, 605
United Kingdom: Eleven Plus exam used in, 386, *386*
United States: age restriction for president of, 630, *630*; attachment styles in, 211, 211*t*; bilingual education in, 297; birth order and intelligence study in, *519*; child abuse in, 536; divorce rate in, 532, *533*; fertility rates in, *528*; foster care in, 538; math competency test results in, 378; moral thought and individualist culture in, 442; psychiatric drug use in children in, 623, 624, *622*; school prayer in, controversy over, 412; Sputnik and improving science education in, 328–29; television viewing studies in, 560
universal concepts, 166
universal constraints: on language, 263
unseen: thinking about, 158–64
Unz, Ron, 297
urban youth: developing biological thought in, 333, *333*
U.S. Constitution: school prayer and, 412
U-shaped developmental curve: idealized, *267*; infants' face-tracking abilities and, 98, *98*; localizing sounds and, 101
utilizational competence, 327
utilization deficit, 350

validity, 32; ecological, 24; forms of, 29–30
valproic acid, 54
values: schools as vehicles of, 412
variables: dependent, 24, 32; independent, 24, 32

V-chip technology: filtering television violence via, 567–68, *568*
Velcro mittens study: causality and, 166; reaching, grasping and, 127, *128,* 137
ventriloquism, 110
VEP method. *see* visually evoked potential (VEP) method
verbal abuse, 536; effects of, 537
verbal aggression, 547
verbal scale: WISC and, 388, 388*t*
vervet monkeys: toy preferences and gender in, *518*
viability: of developing organism, 38–39
victimization: peer, 549–50
victims: of bullying, behavior changes in, 551; of bullying, characteristics of, 550
Victor ("wild child of Aveyron"), 282, *282,* 428
video deficit: mirror test and, 472; in younger children, 561, 562
video games, 559, 569–72, 574; positive effects of, 569–71; violent, aggression and, 571–72
video recording: observational studies and, *22,* 23
violent television cartoons: aggression and, 23, 24
violent television programming, 564–68; childhood and adult aggression and, 565*t*; news reports and, 564, *564*; as public health threat, 567, *567*; responding to influences of, 567–68, *568*; violent behavior correlated with, *565*
virtual *g,* 391
vision, 78–100, 112–13; action coordinated with, 122; aging and, 634; color, 84–86; critical period for, 77; depth perception, 86–91; face perception, 95–100; integrating touch and, 110, *110*; perceiving differences in brightness and acuity, 79–83; perceiving patterns and recognizing objects, 91–95; pruning and, 62; restored, and ability to see, *77*; sensory and perceptual capacities in, 78–79; walking and, 127–31
visiting nurses: prenatal care, child development and, 51
visual acuity, 79–83; changing, in infants, *82*; defined, 79; habituation method and, 80; optokinetic nystagmus method and, 81, *82*; preferential looking method and, 79, *82*; quantitative change and, 11; testing in infants, 79–81, *80*; visually evoked potential (VEP) method and, 81, *82*
visual cliff: active *vs.* passive kittens and, 126–27, *127*; recognizing emotions in others and, 236; situation modification and, 239; social referencing and, 200; studies, *90,* 90–91, 120
visual cortex, *57,* 58, 77; processing acuity and, 83
visual cues: recognizing emotions in others and, 236
visual distortion: effects on sound localization in owls, 103, *103*
visual experience: brain development and, 83
visual flow changes: infants' responses to, *129*
visual flow fields: balance and, 128–29, *129*; walking and, 128
visually evoked potential (VEP) method, 81, *82*
visual system: human, 78
vitalism: in young children, 334, *334*
vitamin A: pregnancy and, 54
vitamin deficiencies: intelligence test scores and, 407
vocabulary, 372–73; commercial television and negative relationship with, 564; educational television and enrichment of, 562; expanding, 372; growth in, 273, *273*; test for, 390
voice onset time (VOT): categorical perception of speech and, *104,* 104–5
von hofsten, Claus, 123
VOT. *see* voice onset time (VOT)
voting rights: elderly population and, 650–51
Vurpillot, Elianne: picture scanning study of, 362, 363
Vygotsky, Lev Semyonovich, 414, 420, 477; on influence of language on thought, 293; sociocultural view of cognitive development and, 337–39; theory of sociocultural development by, 304–5, 312, 340

walking, 125, 131; challenges in, 130; emerging central motor programs and, 121; emerging motor skills and, *118*; seeing and, 127–31; social referencing and, 200; stepping reflex and, 117, *117*
war evacuation residences (England): children living in, *216*
warmth: authoritarian parents and, 507, 508*t*; authoritative parents and, 507, 508*t*; high/low, parenting styles and, 506, 506*t*; neglectful/uninvolved parents and, 508*t*; permissive parents and, 507, 508*t*
War on Poverty: Head Start programs and, 409
Washoe (chimpanzee): sign language and, 289, *289*
Watson, John, 593; "Little Albert" studies of, 138–39, *139*
wavelengths of light, 84
weaning: attachment and, 191
websites: free speech and, 571
Web surfing, 419
Web 2.0 technologies, 419
Wechsler Intelligence Scale for Children (WISC): verbal and performance scales, 388, 388*t*
weight: of older infants, walking and, 121
Wernicke's area: aphasia and, 285
Western cultures: individualistic view of identity in, 356
white matter, 63; frontal lobes, puberty and, 65; gene effects studies and, 69
whites: divorce rates among, 532
whole language approach: in teaching reading, 373, 374
whole-object bias, 275, *276,* 278
Whorf, Benjamin Lee, 290
wikis, 419
Williams syndrome, 285–86, *286*
wills: elderly rights and, 650
Wirt, William, 410
WISC. *see* Wechsler Intelligence Scale for Children (WISC)
within-subjects design, 32; tradeoffs with, 30
witnesses: children as, 360–61
Wolff, Peter, 195
Wolffian ducts, *52*
women: aging and muscle mass loss in, 631; bipolar disorder in, 604; depression, stressful life events and, 644; divorce in childhood and impact on, 534; IQ scores of, 400; language-based tasks and, 401; life expectancy in men *vs.* in, 633; median age of marriage and birth of first child for, over the last century, *525*; memory tasks and, 401; osteoporosis in, 631; rumination and depression in, 607; stereotyping of, in media, 568, 569; with Turner syndrome, 43; unipolar depression in, 603; violent television programming and aggression in, 565*t*; in workforce, *529,* 653
word meanings: conceptual constraints on, 275–77; developmental changes in, 278–80; discovering, 273–80, 300–301; linking features with, 278–80; nature of constraints on, 278; overextensions and, 278, *279*; perceptual constraints on, 275; pragmatic constraints on, 277; underextensions and, 278, *279*; using speaker's gaze and, 277, *277*
words: linking to concepts, 273–75
work: gender roles and stereotyping about, 576–77
workforce: women in, *529,* 653
